It is the policy of Cornell University actively to support equality of educational and employment opportunity. No person shall be denied admission to any educational program or activity or be denied employment on the basis of any legally prohibited discrimination involving, but not limited to, such factors as race, color, creed, religion, national or ethnic origin, sex, age or handicap. The University is committed to the maintenance of affirmative action programs which will assure the continuation of such equality of opportunity.

THE ECONOMICS OF HATCHERY PRODUCED ALGAE AND BIVALVE SEED

by

Julia A. Myers and Richard N. Boisvert

ABSTRACT

The bivalve aquacultural industry in the northeastern United States has been strengthened by declining and fluctuating natural harvests in the surrounding coastal region. Hatcheries in which the bivalves are grown to a small seed size have gained acceptance as a link in the aquacultural process. These firms are potentially able to provide a consistent, reliable source of seed to the bivalve aquaculturist.

This research contributes to an understanding of the hatchery industry by examining factors that influence production costs. The research is based on observations of a working hatchery located in the northeast and on current literature. The data were used to develop the framework for a computer program that can estimate variable production costs. This program required the development of an algorithm that simulates the production process. The model sums costs at different stages of animal growth, which are further broken down into smaller units of time.

There was sufficient information available from the literature and hatchery observations to simulate the overall production system, but expenditure records did not separate costs between stages or between hatchery and open-water field operations. The empirical analysis focuses on estimating costs of algae production, because data on this process were more readily isolated from the rest of the hatchery and because feeding costs are recognized as a large proportion of total costs.

The FORTRAN computer program based on the model focuses on the cost of producing algae feed, but as more details become available about other hatchery production processes it would be a simple matter to incorporate them into the existing FORTRAN code. The computer program combines estimates of the cost of algae production with survival and growth rates and feeding efficiencies to determine the costs of feeding a batch of bivalves to various sizes.

The model is applied to raising Atlantic Oyster seed. Twelve initial simulations were made, assuming different values for important parameters. To explore the implications of these feed cost simulations for the marketing of bivalve seed, some rough estimates of total costs of production per bivalve were developed on the basis of others' estimates of the proportion that feed costs are of total costs. Under the most optimistic assumptions, bivalve seed can be produced and marketed profitably. These conclusions must be qualified by the fact that sufficient data were not available from the hatchery under study to estimate all components of total cost. Collection of these types of data would help in further testing of the algorithm as well as contributing to an overall understanding of hatchery costs at each stage of production. Equally important from a research perspective is the need for better data on hatchery survival rates and the size-age and feeding rates.

THE ECONOMICS OF HATCHERY PRODUCED ALGAE AND BIVALVE SEED

by

Julia A. Myers and Richard N. Boisvert*

*I - INTRODUCTION**

Over the past 25 years, bivalve aquaculture in the northeastern United States has become a reliable supplier of marketable oysters and clams. However, to initiate production, the industry requires adequate supplies of bivalve seed. Seed can be supplied from either natural sets or artificial spawning in a hatchery.

A hatchery operator's ability to produce and market seed as an efficient alternative to naturally-spawned seed requires accurate information about the market, the production process and production costs. As with most managers in a new, rapidly developing industry, hatchery operators have difficulty assembling adequate information to make effective investment and production decisions.

The research reported here contributes to an understanding of the economics of artificially spawned bivalve seed by: a) describing the hatchery industry's development and its production processes and b) formulating a model, associated algorithms and computer code by which operators may calculate variable production costs.

Much of the information about production processes, input requirements and prices was obtained in 1983 from one hatchery on the northeast coast. That being its first full year of operation, the firm's record keeping system was new and not well enough developed to facilitate accurate measurement of the quantities of inputs used at every stage of a bivalve seed's development. However, feed contributes importantly to the total variable cost of bivalve seed (Im *et al*. 1976; Gates *et al*. 1974 and Bolton 1982). Data on algae production were quite good. Thus, the algorithms that calculate algae production and feeding cost are developed in detail. The algorithms can also be used to examine the sensitivity of results with respect to different assumptions about survival rates, growth rates and feeding efficiency.

The remainder of the bulletin begins, in Section *II*, by placing the hatchery industry within the context of the historical decline in the natural bivalve harvest. Various aspects of the hatchery industry affecting the firm and its costs, such as the industry's information network, the issue of property rights and market structure are also discussed. Section *III* describes the production processes using one hatchery as an illustration. This section also outlines choices that affect quality, quantity and timing of inputs and outputs and contains a general discussion of production costs. Section *IV* describes algorithms that simulate the cost of production for each of the system's components. Section *V* presents the empirical application of the program to the American Atlantic Oyster, including tests using data obtained from the hatchery and sensitivity analyses for the program's important variables. Preliminary estimates of total production costs per bivalve are compared with bivalve seed prices to determine at what age (size) the bivalve seed should be sold. Section *VI* summarizes the major findings and their implications for a hatchery's production.

*J. A. Myers is a Research Associate at the University of California, San Diego, Laboratory for Mathematics and Statistics, and R. N. Boisvert is a professor in the Department of Agricultural Economics, Cornell University. The research draws extensively on Myers' thesis (1985) sponsored by the New York Sea Grant Institute under a grant from the Office of Sea Grant, NOAA. The cooperation from individuals at the hatchery where data were collected is gratefully acknowledged. The opinions expressed in the report are those of the authors and not necessarily those of the funding agency nor other cooperators in the research.

II - FORMATION OF THE HATCHERY INDUSTRY

In the northeastern United States, the long-standing clam and oyster fishing industry has given rise to the development of the bivalve hatchery industry. Over harvests and increased urbanization, with the consequent decline in the once-abundant natural bivalve population, have forced harvesters to look for alternatives. Among these alternatives are government regulation and incentives, but perhaps the most important alternative is the aquacultural industry, which is replacing traditional methods of harvest. Recently, hatcheries producing bivalves to seed size only have emerged as an alternative to natural bivalve spawnings and also as a link in the aquacultural production of marketable bivalves.

Background

Clams and oysters are harvested in all 14 states along the Atlantic Seaboard (U.S. Dept. of Commerce 1979). The most common oyster is the American Atlantic Oyster (*Crassostrea virginica*). Four species of clam--hard, soft, surf, and ocean quahog--constitute 99% of total U.S. landings by weight. The northern hard shell clam (*Mercenaria mercenaria*) accounts for 53% of the landings, although it constitutes only 17% of their value (Dressel and Fitzgibbon 1978).

Long Island, New England, and the Chesapeake Bay have historically been centers of clam and oyster fisheries (Ritchie 1977; Manzi *et al.* 1982b). Long Island Sound (the waters between Long Island and Connecticut), and Great South Bay, (the waters between Long Island and Fire Island), are the most productive of the New York areas (Figure 1). The seabeds there are hard, shallow and scattered with culch material to which the young animals attach (Korringa 1976). Additionally, the strong tidal currents carry abundant food into the bay (Bardach *et al.* 1972) and the bivalves are protected from many predators because the salinity is lower than in the surrounding ocean water.

Bivalves, especially oysters, have been an important food source for the New York Bight coastal region. Oysters were used by Native Americans for food and trade and later by the colonialists (Terry 1977). Clams were fewer in number than oysters, but by the 1900's the rise of the cannery industry encouraged the growth of the clamming industry (Dressel and Fitzgibbon 1978).

The rise in clam production was interrupted after red meat shortages of the 1940's put increased pressure on the shellfish industry. Landings in the New York Marine District decreased from 6.8 million to 3.3 million pounds between 1943 and 1945 (Figure 2). Although landings later increased, the industry continued a pattern of boom and bust. In 1976 Long Island harvests reached a peak of 8.4 million pounds, worth about $16.8 million (Freedman and Morris 1983). Great South Bay was considered the most important hard-shell clam industry in the world. It harvested 80% of Long Island's total landings, which represented 50% of the U.S. total (U.S. Dept. of Commerce 1974). Since then, the Long Island clam harvest has declined; by 1982, harvests were down by 60% from 1976 levels (Figure 3).

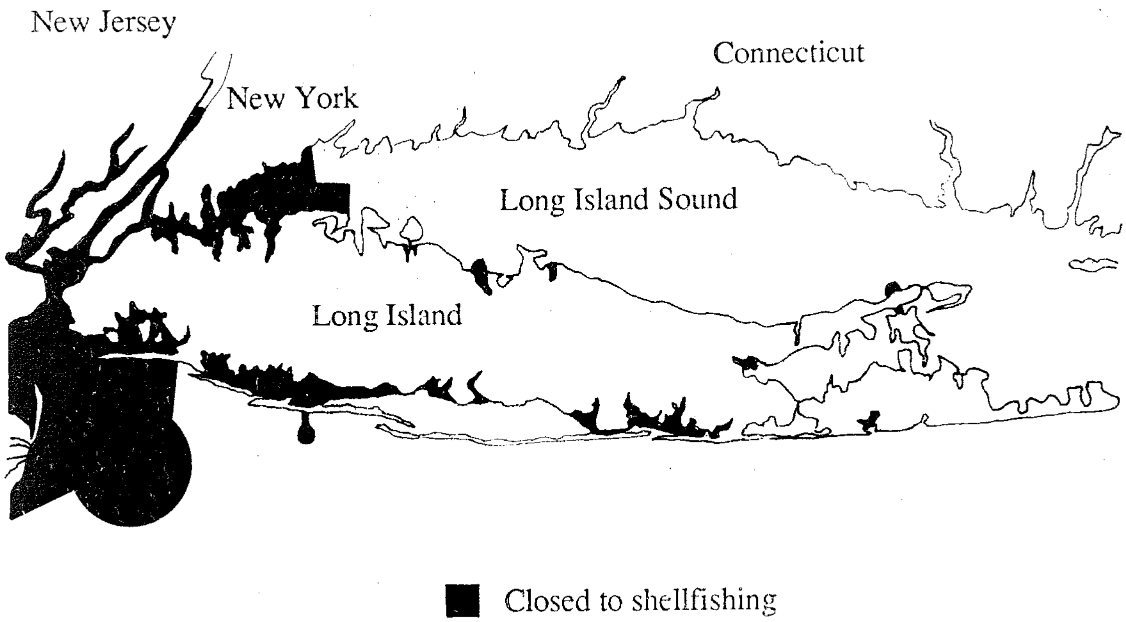
After a peak in 1904, oyster harvests in New York remained fairly stable between 1921 and 1952 but experienced a near-collapse in the 1960's (Figure 2). Revival of the industry through aquaculture has increased landings. Today, oyster production in the New York region is based entirely on aquaculture (Terry 1977).

Population Dynamics

To understand the dramatic changes in the Long Island clam and oyster industries, one must examine the interaction among competing factors that determine the cyclic pattern of bivalve populations. Although population fluctuations occur naturally, they have been exaggerated through over harvest and destruction of natural habitat.

An inherent problem of common property fisheries is overuse (Hardin 1968), which leaves too few animals unharvested for the species to repopulate. This problem is acute around Long Island because bivalves in

FIGURE 1. MAP OF LONG ISLAND COASTAL REGION



Source: Terry (1977)

the cool waters require a long maturation period and because a large proportion of the population must be left unharvested in order to sustain the population. Thus, one major reason for the periodic decline of the clam and oyster populations is the likelihood that harvests will occasionally exceed the maximum sustainable yield.

Competition with man has decreased the natural habitat of clams and oysters and adversely affected bivalve populations. As urbanization and shoreline use in the New York area intensified, natural spawning grounds were reduced. Siltation, which is particularly harmful to young spat, increased; and saltwater intrusion caused by the removal of sandbars decreased protection against natural predators (Freedman and Morris 1983). Because toxins accumulate in the flesh of oysters and clams, the increased sewage effluent and agricultural runoff in the area have increased mortality rates as well as decreased the marketability of the bivalve. The actual numbers of oysters and clams available for harvest have been reduced further through the closure of contaminated natural spawning beds (Figure 1).

Demand Considerations

While many factors affecting the bivalve population dynamics have resulted in a reduction in their supply, the industry has also been affected by demand considerations. For example, although the income elasticity of demand for clams is positive, it is relatively low, giving rise to only a slow growth in demand for clams over time due to rising per-capita income and increasing human population (Gates *et al.* 1974). The income elasticity of demand for oysters is positive as well, but per capita consumption has actually decreased

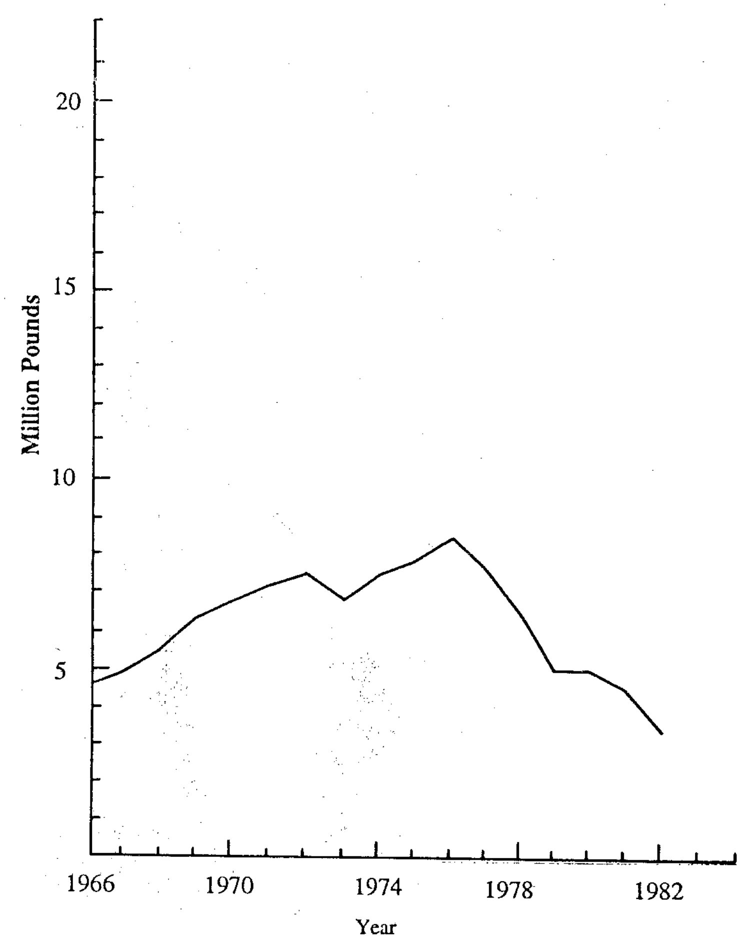
FIGURE 3. LONG ISLAND CLAM HARVEST



Source: Freedman and Morris (1983)

(Im and Langmo 1977). This decrease might have been caused by either the decrease in supply (Gates *et al.* 1974) and the associated rise in price, or by a change in consumers' tastes due to the fear of eating contaminated animals.

Alternatives

These problems have led to a disappearance of, or change in, the traditional shellfish industry. The scarcity of the hard clam has caused a shift to other species, such as surf clams (Dressel and Fitzgibbon 1978). Production has shifted southward to less-populated regions where competition for habitat is not so keen (Manzi *et al.* 1982a). Also, oyster imports have increased (Im and Langmo 1977).

Options to halt the gradual disappearance of the existing bivalve industry do exist. One option is a comprehensive government management plan to stop the decrease in, or even increase, the natural bivalve populations. Aquacultural production of marketable bivalves and hatchery production of bivalve seed are also viable alternatives, but they both require radical change in traditional harvesting techniques.

Regulation

Because most clam and oyster beds are common-property resources, they have suffered, as most common-property resources have, from over-use and abuse. Although size, time and method of catch are regulated, no consistent policy for predator control or return of culch material to the beds has been in force (Matthiessen 1970). Furthermore, these regulations have often been ineffective because of inadequate knowledge, failure to enforce existing laws, lack of cooperation and an absence of comprehensive planning.

The Regional Marine Resources Council's Shellfish Committee, created in the 1970's, partially filled the void by identifying 18 guidelines for improving the industry (Regional Marine Resources Council 1974). A Long Island clam union exists to aid members of the industry. On the consumer side, identification of potentially harmful pathogens, public health inspections and enforcement of closed beds will help maintain consumer confidence and increase demand.

To protect the industry, some Long Island governments have purchased young shellfish seed in order to seed public grounds (Smith 1982-83; Goldstein 1983). The population could also be increased by controlling predators, working the bottom for better spawning success, transferring animals to non-polluted grounds and controlling pollution, saltwater intrusion and siltation of habitat.

Unfortunately, implementation of such non-traditional resource policies is politically arduous and requires placation of special-interest groups and cooperation among affected parties. These measures are often expensive to establish and to enforce. The overall benefits to society from an increased bivalve population and the resulting strengthened harvesting industry must be measured against the costs of implementing any resource-regulating mechanisms.

Aquaculture

Aquaculture, the growing of organisms in water under controlled conditions, offers an alternative to traditional bivalve harvesting techniques. The primary benefits of controlling the environment are increased product supplies, although factors adversely affecting quality, such as predators, crowding and parasites, may be reduced.

The viability of an aquaculture industry may depend on the granting of exclusive rights to harvest or to develop a section of the ocean bottom aquaculturally. Marine resources have traditionally been common property (Terry 1977), but sedentary marine life on the bottom may be considered private property, although this right is difficult to substantiate (Hanson 1974; Terry 1977).

The states around the New York Bight area and towns on Long Island have a history of granting bottom leases to private individuals (Kochiss 1974; Terry 1977; Gates *et al.* 1974). In New York, the Department of Environmental Conservation grants leases on the condition that the water quality is good and that no naturally-productive shellfish beds exist (Terry 1977). Great South Bay is held in trust by local townships; harvesters have full bottom rights to certain areas.

In general, economists support private ownership to increase efficiency and productivity (Agnello and Donnelley 1976; Terry 1977). Private beds experience five to ten times greater productivity (Dressel and Fitzgibbon 1978), probably because private harvesters can use less labor-intensive methods than can the public harvesters, who are required by the government to use inefficient harvesting techniques to control harvest quantity. Furthermore, without the assurance of exclusive rights to a harvest, there is no incentive for private harvesters to return culch, to control predators, to establish seed beds or to purchase seed to supplement the natural sets.

As stated above, the viability of the industry is demonstrated by the fact that all oysters on Long Island are currently produced by aquaculture (Terry 1977; Pillay 1976), and all oyster aquaculturists produce some hard clams (Korringa 1976). However, there has been increasing opposition led by local harvesters to the leasing of marine bottom, even of non-productive beds. Few leases have been granted recently (Terry 1977), and if these beds continue to remain in public control and open to all harvesters, the community must either exert better management controls or expect diminishing supply. On the other hand, private ownership might lead to an increase of marketable species but a decrease or disappearance of other naturally-occurring species.

Hatcheries

Potential advantages to hatchery-produced seed include greater reliability of production and better quality control. The development of the hatchery industry (which grows clam and other larvae into bottom-dwelling seed large enough to be planted in open waters for later cultivation or harvesting) has come in response to natural reproduction failure in open water (Loosanoff and Davis 1963a; Henderson 1978). Hatcheries can potentially achieve better quality control, decreased mortality and faster growth (Bardach *et al.* 1972; Donohue *et al.* 1981), thus offering aquaculturists a reliable source of bivalve seed. Furthermore, local governments can supplement declining natural spawns with hatchery-produced seed, a practice local harvesters generally favor as an alternative to direct governmental support of open-water growout in areas where a few individuals can affect the local bivalve market (Miller 1977; Rhodes 1974).

Worldwide demand for oyster and clam seed is growing at an increasing rate because of decreasing natural stocks and improving hatchery techniques. Henderson (1978) has estimated the annual world market for hatchery seed to be $2 billion, or 25% of the annual U.S. whole clam and oyster harvests. In the U.S., hatcheries exist in the Southeast, the Northwest and in parts of the Northeast. The U.S. leads in seed production, having pioneered many clam hatchery techniques, but its oyster techniques are still considered "primitive" (Bardach *et al.* 1972).

Opinions differ as to the sufficiency of seed availability. Clam seed is more readily available than oyster seed (Terry 1977), except for seed larger than 10 mm (Castagna and Kraeuter 1977; Manzi *et al.* 1982a). Supplies of oyster seed have proven unreliable and insufficient to meet demand at current price (Donohue *et al.* 1981; Im and Langmo 1977). The demand for hatchery-produced seed is cyclical and increases during natural set failures (Henderson 1978). If hatcheries could produce a reliable, inexpensive product that is more attractive to growers than natural seed, they could capture a larger share of the seed market.

Hatcheries currently operate with less than complete information for two reasons: a) lack of cooperation between affected parties in the industry (Henderson 1978); and b) inasmuch as no two hatcheries are operated exactly alike (Terry 1977), such information as is available from one is not entirely applicable to another. Partly due to this lack of information, hatcheries are only marginally cost-effective (Terry 1977). Cooperation should be improved between hatchery operators and buyers, researchers and the government (Henderson 1978). This in turn should affect the flow of information and help industry development.

Despite the problems faced by hatcheries, many in the field believe that they will continue as a viable industry (Terry 1977). Genetic breeding and development of domestic bivalve strains are future potentials of the industry (Terry 1977). The development and success of the hatchery industry depends on the continued demand for seed, encouragement by government and the scientific community and the success of hatchery operators. The success of the individual operator depends in large part on an ability to compete in the market place. To be competitive, the hatchery operator must be able to make the best production decisions based on an accurate assessment of production costs. This is the subject of the following sections.

III - HATCHERY PRODUCTION OF BIVALVE SEED

Raising oyster and clam seed under controlled conditions requires technically-sophisticated, delicately-monitored production processes. The purpose of this section is to describe these processes, using the hatchery from which data were collected as a model. Although production systems vary among hatcheries, especially in algae and culch preparation and in facility and system designs, most operations are universal to all hatcheries. Techniques are varied primarily to take advantage of available natural resources at the site.

The Hatchery

The bivalve seed hatchery, from which data were collected for this study, was the outgrowth of an experimental plant begun in the late 1970's. This model facility was used to help train staff and develop techniques utilizing the available natural resources in the surrounding area.

Construction of the permanent hatchery was completed in 1982. The building used for seed production has approximately 500 square meters of indoor floor space. There is an ample outdoor work area, as well as room available for expansion. The hatchery began partial production in 1982, and the first full production year was 1983. Both oysters and clams are grown, but production is now concentrated on oysters.

The hatchery is located a few hundred yards from a bay. The ownership of the bottom rights to part of the bay led to the development of a field operation ("outgrow") where some of the seed produced in the hatchery is grown to maturity. Most of these outgrow operations are conducted separately from those of the hatchery.

The Hatchery's Production System

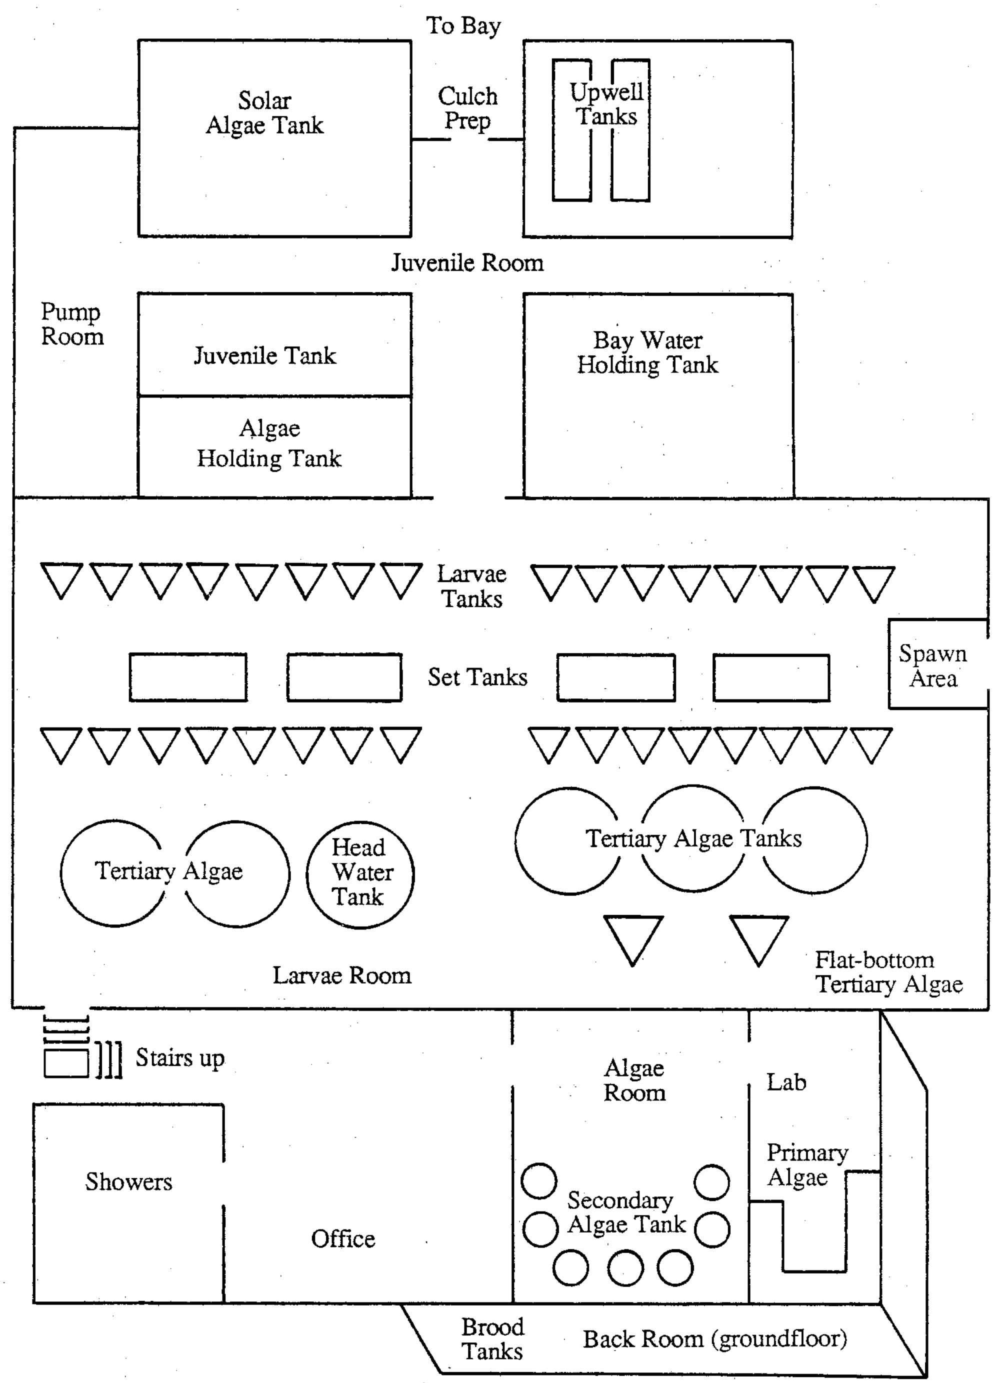
The production process can be divided into six life-cycle stages for the bivalve:[1] 1) broodstock maintenance and conditioning; 2) spawning; 3) larvae development; 4) setting; 5) juvenile development and 6) field (or outgrow); and two support stages: 1) algae production and 2) culch production. Figure 4 shows the location of each production stage within the hatchery.

To maintain a low mortality rate, young bivalves must be treated with care during all phases of production, including inspection, cleaning and transfer. Exposure to severe environmental conditions or fouling by foreign organisms, such as fungus, bacteria and predators, can cause death or deformation of the animals or a poisoned product. Thus, particular attention must be given to cleanliness at each stage of production and to selec-

---

[1] Because the differences between clam and oyster production are minimal, the two processes will be treated as one throughout the remainder of this analysis.

FIGURE 4. PRODUCTION LOCATIONS IN THE HATCHERY



tion of non-toxic materials for all equipment that comes in direct contact with the animals. The quantity and quality of inputs used, such as energy, algae, culch and other materials, depend on the biological requirements of the bivalve, the existing environmental conditions and on the hatchery's ability to purchase or produce those inputs. Inadequate or poor quality inputs will affect the survival of the bivalves.

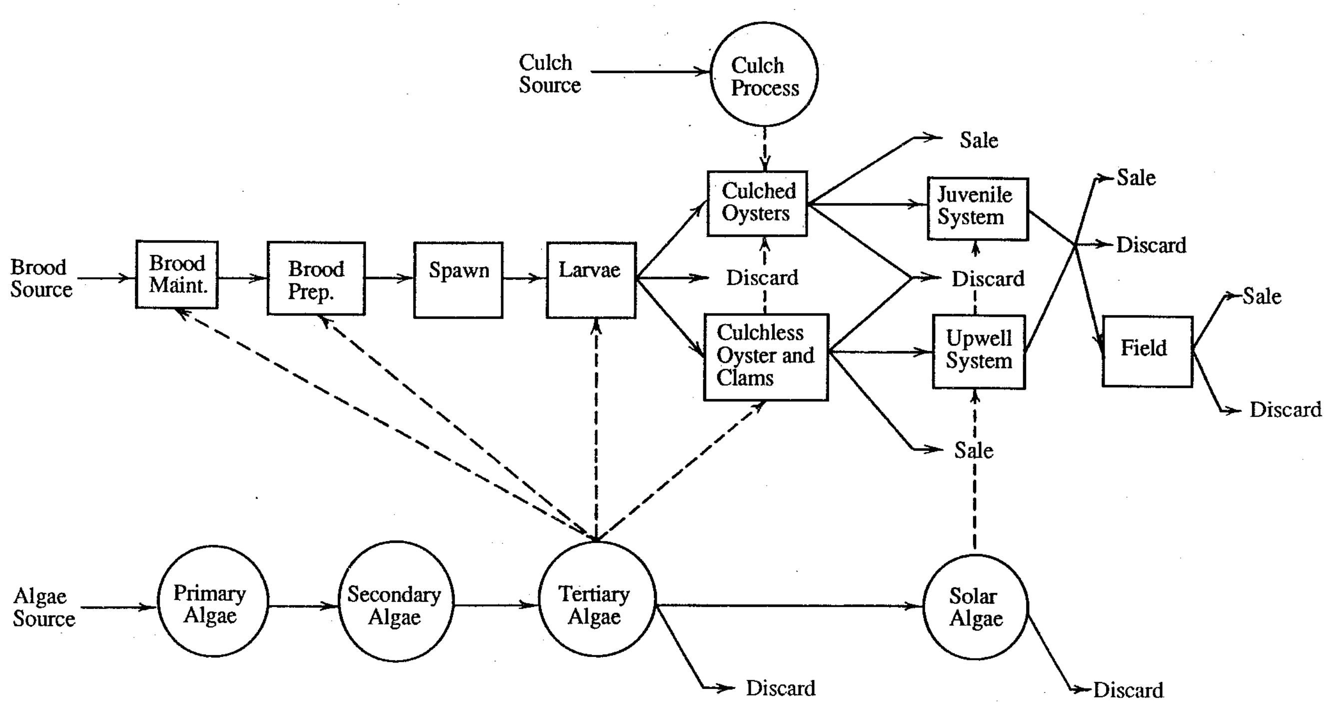
As with most biological production processes, there is a trade-off between achieving maximum production and the cost of inputs. For instance, higher densities improve efficiency in the use of inputs such as water and labor; however, a high density decreases the survival and growth rates of the existing animals. The hatchery must weigh the marginal cost of providing ideal environmental conditions against the resulting increase in the value of the marginal output.

Proper timing of production is critical in two respects. First, if the hatchery begins production too early in the season, the animals will be ready for transfer to the juvenile tanks or outgrow facility before the water has reached a suitable temperature. Extending production too late may leave the hatchery with unsold inventory. Second, new spawnings and transfers between stages must be timed so as not to exceed the system's capacity in terms of space or ability to produce sufficient inputs. The optimal age of transfer depends in part on the cost of maintaining the animal. The best way to understand the production system is to examine each of the components separately. (Figure 5 shows the flow between the production stages.)

Algae

Production of algae for feed in sufficient quantity and quality is important to the bivalve at all stages of growth and is one of the principal problems in profitably growing animals to market size entirely within a closed system (Gates *et al.* 1974; Epifanio 1975). Not much is known about the specific food requirements of the bivalve (Galtsoff 1964), especially about the adult bivalve (Epifanio 1975), but in the work that has been done, bivalve algae consumption is measured either by the number of cells consumed per animal or by the algae concentration made available to the animal. Existing estimates of the number of cells consumed by

FIGURE 5. FLOW BETWEEN HATCHERY PRODUCTION STAGES



oysters and clams at different stages of animal growth are in Table 1. Using the second and most common method, optimum algae concentrations for oyster larvae are given in Table 2.

The amount of algae assimilated, i.e., actually used for growth by the animal, is estimated at between 70% and 90% of the amount consumed (Epifanio 1975). Consumption is less than the filtering rate (the cells filtered per volume of water pumped), and the filtering rate in turn is less than the pumping rate. Filtering efficiency is affected by environmental conditions and was measured at between 34% and 58% by Baab and Associates (1973).

For bivalve feed, a mix of algae species is preferable (Ukeles 1975). The digestibility and nutrient value of the food depends on the chemical composition, size, texture, taste (Epifanio 1976), cell wall and toxicity (Ukeles 1975) of the algae species. Juveniles are less sensitive to algae quality and size than are larvae, which require cells sized from 6-10 microns in diameter (Breese and Malouf 1975). Clams are generally less particular than are oysters about the quality of algae fed (Ukeles 1975).

The quantity of algae that the hatchery must produce to feed the bivalves depends on whether or not sea-water containing naturally occurring algae is made available to the animals. The proportion of its diet an animal is able to receive in this way depends on the concentration of algae in the seawater, on the pumping and filtering abilities of the animal, on the seasonal variation of that concentration and on the amount of water to which the animal is exposed. Also, some additional algae must be produced and held in reserve in case main supplies are contaminated. Producing excessive amounts can be costly, because algae can be stored only a few days.

The hatchery's algae stage is managed by a single employee, who spends more than one-half the total working hours exclusively

Table 1. Daily Consumption of Algae Cells by Oysters and Clams

Stage/Age of Oyster	Equivalent Stage at the Hatchery	Algae Cells Consumed Per Day: Oysters	Clams[a]
Larvae			
2 days		1.0×10^4	
12-15 days	Larval	4.0×10^4	
set size		5.0×10^4	
Spat		2.0×10^5	1.0×10^5
3 weeks	Setting	3.0×10^6	
8 weeks		2.4×10^7	
Seed	Juvenile	8.0×10^7	6.0×10^5
Adult	Juvenile/Outgrow		1.0×10^7
3 inches		1.1×10^8

on algae production. The batch method, in which algae is cultured to a maximum density using successively larger containers, is used. Not all algae at a maximum age and density are used exclusively for food; instead, some are used to innoculate a larger tank.[2] This "modified batch" strategy requires additional labor (Matthiessen and Smith 1979).

The second-floor laboratory is where algae samples are analyzed for contamination and proper densities, nutrient solution is prepared to supplement the algae cultures, and initial algae stock is stored. Four different varieties are cultured: *Thalassiosira pseudoma* (diatom), *Pavlova lutherii*, *Pavlova lutherii Hoptaphyceae* and *Isochrysis galbana*. The latter represents 50% of the algae grown and 50% of the animal's diet. Because young animals require small algae cells, the diatom is used only during the juvenile stage.

The primary algae production stage begins with tube cultures. Algae, in nutrient-rich well water, are allowed to mature two weeks to a maximum density of 3 x 10^5 cells/ml. The culture is then transferred to sterilized flask containers. After one week, this culture matures and is transferred to carboys. Water must remain cool and sufficiently aerated. Cool fluorescent lighting provides the algae with artificial sunlight 24 hours each day.

The secondary stage, located in the algae room next to the laboratory, consists of seven 757-litre tanks. Each tank is innoculated with 16 litres of primary algae culture; nutrients and well water are added. The number of tanks used depends on near-term food requirements. Optimum algae density of 4 x 10^5 cells/ml is reached in one week.

The secondary culture flows to the ground floor to innoculate the 3,785-litre tertiary algae tanks. The requirements at this stage are similar to those for previous cultures; and when a maximum density of 5 to 8 x 10^5 cells/ml is reached, the tertiary, or "direct-feed", stage is used to feed the bivalve broodstock and the animals at the larvae and set stages. It is also used to innoculate the next culture stage. After one week, any algae remaining are discarded.

The final algae tank is a sunken 49,205-litre tank in the juvenile room. This "solar" tank is innoculated from the tertiary tanks and allowed to bloom under natural sunlight provided by large, sloping windows over the tank. Maintenance is similar to that in other stages. When a suitable density is reached, the entire amount is transferred to the algae holding tank located in the same room; the solar tank is then reinnoculated. The juvenile bivalves are fed directly from the holding tank. After one week, the remaining algae are discarded.

Broodstock Maintenance and Conditioning

The quality of the bivalve produced depends to a degree on the genetic quality of the parental stock, which is selected on the

[2] In contrast to techniques that centrifuge large quantities of seawater to concentrate naturally-occurring algae, this method selects only the best species of algae. The centrifuge process, which is commonly used on Long Island, is less expensive (Matthiessen and Smith 1979), but it requires an abundant and reliable source of naturally-occurring, desirable algae. The batch or modified batch process offers certain advantages for feeding efficiency because higher densities of algae can be obtained. With these processes, algae can be produced at densities of 10^7 cells/ml, as compared to densities in seawater of 10^4 cells/ml (Gates et al. 1974).

basis of size, shape and growth potential. The broodstock is kept in rectangular 825-litre tanks of aerated, filtered water. Cool water temperatures are maintained to prevent spontaneous reproduction.

Before spawning can occur, the mature adults must be "conditioned"; the water temperature is increased to 26-29°C, and the food supply is also increased. The conditioning time varies according to the temperature and the amount of food used, but oysters require approximately 35 days (Gates *et al.* 1974).

Spawning

Once the male and female bivalves have been conditioned, the spawning process takes two employees one to three hours to complete. Conditioned adults are induced to spawn by either introducing a sharp temperature increase or by adding previously-collected sperm (Breese and Malouf 1975). One female clam can produce as many as 24 million eggs at a time (Loosanoff and Davis 1963b). Within 24 to 48 hours, the gametes become free-swimming larvae.

Larvae Development

During the larvae stage, algae-rich seawater is circulated about the mobile animals ("veligers"). In the larvae room are 38 conical, 340-litre larvae tanks and two 700-litre, flat-bottom larvae tanks. These tanks are filled with warm, filtered seawater, which must be heated when seawater temperature is below 25°C. Approximately 14 litres of algae are added to each tank/day.

Oyster and clam larvae are maintained close to ideal densities for fastest growth and survival, viz., densities from 0.4 to 15 animals/ml and 5 animals/ml of water, respectively (Gates *et al.* 1974; Matthiessen and Toner 1966). Growth and survival rates at this and subsequent stages are affected not only by density and by food quantity and quality, but also by the temperature and available oxygen. Thus, water is maintained at the ideal temperature, and aeration is supplied continually to all tanks.

Maintenance of the larvae is labor-intensive. Besides daily feeding and monitoring, every 48 hours the tanks are cleaned, the larvae are sorted by size, and the dead animals are removed. This takes two employees nearly a full day to complete, depending on the number of tanks in use. Animals of similar size are collected together from different tanks and are then returned to a newly-filled tank, and algae are added. This culling process is an essential feature of the production process because it, in large part, determines the quality and the quantity of the final output.

The most critical period for the larvae occurs at metamorphosis, when the bivalves change from free-swimming larvae to bottom-dwelling spat. Setting occurs at 7 to 10 days for clams (Bardach *et al.* 1972; Gates *et al.* 1974) and 10 to 20 days for oysters (Gates *et al.* 1974). The clams at this stage measure 200 to 215 microns (Bardach *et al.* 1972; Gates *et al.* 1974) and oysters 300 to 325 microns. Prior to this metamorphosis, the animals must be transferred to the set tanks, which have been filled with culch.

Culch

Culch is the material onto which the oyster larvae set and attach permanently. Thus, before the larvae can be transferred to the setting tanks, culch is prepared. The choice of culch material depends on the type of grow-out anticipated rather than the relative cost of the materials (Matthiessen 1970; Gates *et al.* 1974).[3] Before 1960, whole oyster or clam shell was used exclusively for bottom culch material (Matthiessen and Smith 1979); other techniques, such as the suspended-string method, could be used in lieu of bottom culch. Today, choices for culch include a variety of shell sizes, artificial materials and "culchless" oysters.

The culchless oyster is an oyster with no attached culch, that is, one that has been induced to set on a material, such as plastic

[3] Clams do not require culch since they do not attach firmly.

sheeting, from which it can be removed easily. Culchless oysters can be grown at greater densities than the culched variety inasmuch as clumping, which crowds and deforms the spat on the culch, is less of a problem. Culchless oysters may be less expensive to produce because culch production costs are avoided, and because shipping and handling of the culchless oyster is less costly. However, once transplanted, the culched oyster has a better chance of surviving, especially in waters with high siltation (Matthiessen 1970). Thus, culchless oysters (and clams) should be raised to larger sizes in the hatchery, potentially offsetting any other savings.

The preparation of culch is tedious, taking about 12 minutes to produce one litre of sorted, crushed shell. The prepared culch is then cleaned and spread on the bottom of the set tanks at densities of 200 to 350 ml/square foot.

Setting

Prior to setting, the larvae are transferred to eight 825-litre tanks filled with warm, filtered, aerated water at densities of 2 to 18 million animals per tank. Maintenance is similar to that for larvae; the same algae mix is used, although cleaning is less frequent (every 72 hours). The animals are fed 70 litres of algae/day/tank during the first week; this is increased to 140 litres by the second week.

Because the animals are delicate at this stage of their life, their transfer too early to the juvenile tanks could reduce the overall survival rate. The hatchery does not heat the juvenile tanks and must wait for the bay water to heat sufficiently by natural means before young spat can be transferred. However, if the animals remain too long in the set tanks, they cannot receive the large quantities of flowing water and algae necessary for rapid growth, nor can the tanks be used for subsequent batches. Animals as small as 300 microns and as large as 1.9 mm have been transferred out of the set tanks in the hatchery.

Juvenile Development

From the set tanks, the young spat are transferred into either the juvenile tanks or the upwell system, or they are sold. Most oyster and clam seed are sold at about 3 mm; smaller animals than this would experience too low of a survival rate.

The juvenile tank has a capacity of 26,500 litres. The culched oysters are placed in trays that measure 0.5 x 0.6 m; these trays are then placed on the bottom of the juvenile tank. The tank is filled with enough sieved bay water to cover the trays and is aerated. Approximately 75 litres of algae are added per day to achieve a cell count of 2×10^6 cells/ml. The tank is cleaned twice per week, at which time the animals are washed and culled for death, fouling, and deformation. By the time the animals are ready for sale or transfer to the field, there has been a significant reduction in their numbers.

The upwell system is used only for clams and culchless or micro-culched oysters. The spat are held in screened-bottomed buckets, which are suspended over 825-litre rectangular tanks. Water from the bay holding tank is siphoned into these tanks, creating a continuous flow of water that aerates the spat. This sieved water is at bay temperature: 17^{o}C in May and 28^{o}C in August. Algae from the holding tank are added at a rate of about 7,600 litres per day. Animals have been kept in this system until they have reached 2.3 to 8 mm in diameter, and then they have been sold or transferred to the field.

The Hatchery's Physical Systems

The facility was designed for efficiency and flexibility to allow for changes in production techniques in response to new scientific information, environmental conditions or market changes. Simple changes in internal arrangements, made possible by movable tanks that can be used for a variety of functions, can streamline production. The hatchery was designed to facilitate easy cleaning. Energy, water and air systems were coordinated to maximize efficiency.

Energy System

The amount and the type of energy used in the hatchery depend on the production method and on the prevailing environmental conditions. Natural lighting and heating are used wherever possible. Because the bay water temperature is cool, the hatchery must heat large quantities of water to fill the brood, larvae and set tanks.

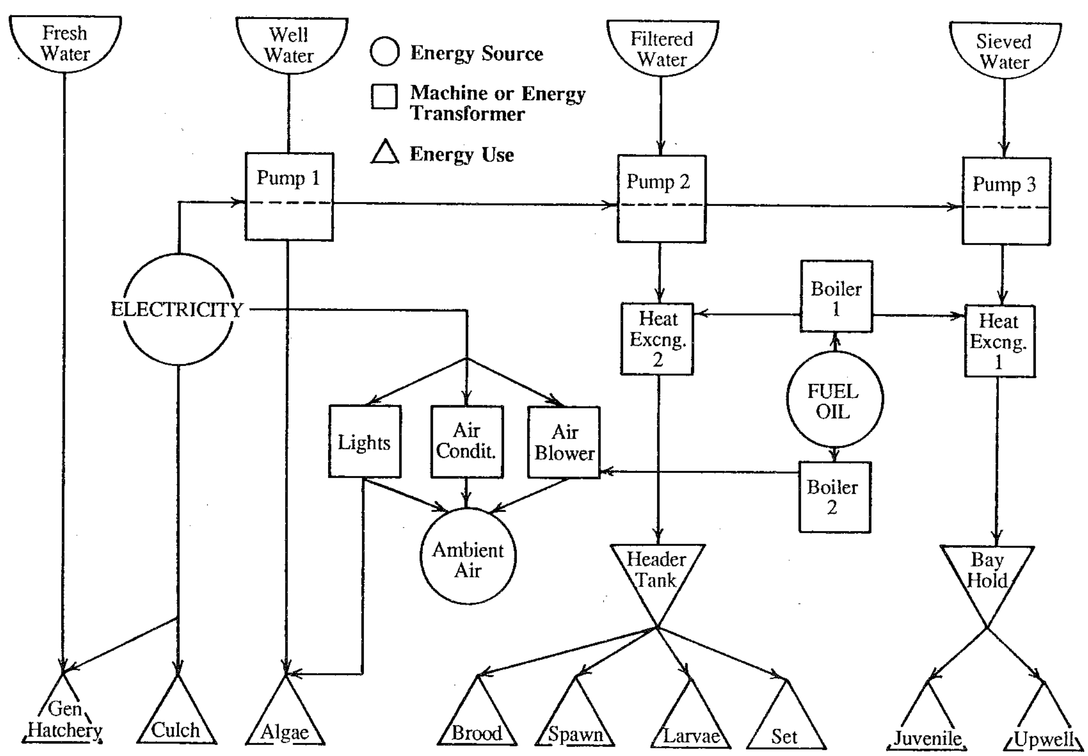
The energy flow is complex (Figure 6). Heat inputs include electricity for lighting and machinery and fuel oil for running the boilers to heat water and ambient air. Cooling inputs include air conditioners, bay water and ambient air. The relative contribution required from each of these sources to maintain ideal water and air temperatures is a function of the season. It is possible to determine the amount of electricity and fuel oil required if initial temperatures, final temperatures, and heating and cooling capacities are known.

Water System

Water is used in all phases of production: for all animal stages, for algae production and for cleaning. Water, the quality of which is critical to all hatchery operations (Bardach *et al.* 1972), can be sterilized with ultraviolet light or with chemicals. Fresh water for cleaning is obtained from a reservoir at no cost to the hatchery, and three pumps bring water from the bay (Figure 6). The first pump is for deep-well water, which is used exclusively for algae production. It is the purest of the three bay waters and is never heated. Pump 2 filters out particles greater than 1 to 5 microns; this water is used for larvae, brood and set tanks. The third pump delivers water to the juvenile room and sieves out particles greater than 700 microns.

The facility is designed to minimize the electrical costs of pumping. By using a series of different levels, water can be siphoned for various uses once it is within the

FIGURE 6. ENERGY AND WATER FLOW WITHIN THE HATCHERY



facility. Gravity is also used for the transfer of algae from the secondary to the tertiary stages and from the tertiary to the solar stage.

Air Flow System

If water is not kept in constant flow, the hatchery must provide aeration. Although the hatchery's air system is not elaborate, it is essential to algae and animal growth. Depending on size, all tanks are provided with a certain number of air tubes, except for the upwell system, which receives a constant flow of water. Air is pumped through these tubes from an air compressor that operates 24 hours per day. To reduce electricity consumption, the hatchery replaced its 5-HP air compressor with a 1-HP compressor, which has proven sufficient for the hatchery's needs.

Costs and Input Considerations

Before the decision to build a hatchery is made, a complete financial assessment should be conducted, including estimates of the initial investment cost, operating expenses and expected earnings. To date, existing hatcheries were estimated to have an average initial capital investment for building and equipment greater than $100,000 (Matthiessen and Smith 1979), but technically-advanced hatcheries, such as this one, may cost even more. Using land with direct access to the ocean can add considerably to the total price, although in this case, the land was already owned.

Hatchery operating costs were estimated at between $2,700 and $10,000 per month for most facilities (Matthiessen and Smith 1979). The actual amount depends on the hatchery's output and design, on the existing environmental conditions, and on unforeseen production risk beyond the control of the operator.

To date, there are only a handful of published estimates on the cost of bivalve seed, and the average costs per animal range from $0.0005 (Im and Langmo 1977) to $0.01 (Matthiessen 1979) for smaller seed and from $.029 to $0.25 (Gates *et al.* 1974) for larger seed. The most comprehensive estimates have been made in recent years by Im and Langmo (1977), Im *et al.* (1976) and Bolton (1982). They have attempted to estimate costs at each stage of production (e.g., brood, larvae etc.) using an economic engineering approach based on small, experimental hatcheries both on the Pacific and Atlantic coasts.

These studies are an important first step, but they fail to determine the cost of producing animals to different sizes in the same stage. This information is particularly critical at the final stage, that is, just prior to sale or transfer to outgrow facilities, because an aquaculturist purchases seed from a hatchery at a size in accordance with his production method, locality and production goals. It appears that 3 mm is a common size at which to sell the spat. Those who purchase larger seed face significantly less risk of mortality in open waters since they are more resilient to predation, siltation and climatic changes (Matthiessen and Smith 1979).

When larger seed are produced, it is usually because a) the hatchery cannot find buyers for seed not previously contracted for sale (usually the hatchery overproduces some animals to leave a margin of error), b) environmental conditions are such that the hatchery cannot transfer seed to their own "growout" facility or c) it is experimenting with growth techniques for larger animals. In other words, production to a larger size is not necessarily desirable but may be preferable to disposal of the animals if the hatchery can cover its costs at the margin.

Classifying Productive Inputs

An important first step in estimating the cost of raising bivalve seed to different sizes is to identify the input requirements for each stage of production. As outlined in Table 3, production of bivalve seed can be separated into five production stages and two support stages: 1) broodstock conditioning, 2) spawning, 3) larval development, 4) setting, and 5) juvenile development; and 1) culch and 2) algae preparation. Because input quantities change over time, they will also change over the duration of most stages. Therefore, in this analysis, the stages are broken down into smaller units of time, or periods. At the end of a period, there is an associated size and age

[a]See text and Figure 5 for identification of stages. General hatchery inputs are independent of stage. Intermediate inputs are produced in support stages.

of animal, as determined by the growth rate experienced in the hatchery. The cost per animal at any age can be estimated by measuring the inputs that are used in a period.

As with most production systems, inputs can be classified as either fixed or variable. Fixed inputs are those whose quantity cannot be changed during the length of time under consideration since the cost of quick variation in their amount is large as to make such variations impractical (Mansfield 1979). Here, we are interested in smaller seed (produced in less than 4 months) as well as in larger animals that must be left in the hatchery longer. For convenience, the length of time under consideration is taken to be one year. Thus, fixed costs are assumed to include depreciation on building and equipment, taxes, and rental charges.

Some inputs are also fixed once a batch is started and so either do not vary with output or vary insignificantly. These inputs include general hatchery maintenance, such as for machinery and general hatchery cleaning. It is difficult to isolate these costs in terms of their applicability to any particular stage or period of the bivalve's life.

Variable costs differ in how much they are affected by the level of production output. First, because of the nature of hatchery production, which uses a modular-style (e.g., separate tanks), many inputs are only secondarily related to the number of animals within the system. For example, a larvae tank requires a certain amount of labor for cleaning and a certain amount of heated water no matter how many animals are in each tank even though the number of tanks used does depend on the total number of animals. Second, some inputs are related to the area where the animals are located and must be used no matter how many tanks are in that area, such as space heating. Third, some events take place only once and are not significantly affected by the number of animals, for example, sampling. Finally, there are those inputs, such as algae consumption, that vary directly with output.

It is the inputs that vary according to the number of animals in the system that are of greatest interest to this analysis, since it is these inputs that vary most with animal size. Inputs that do not vary directly with output are shared according to the relative length of time that the animal is retained in the hatchery, rather than the total output or the animal's size.

For this study, inputs are divided into six primary categories: electricity, fuel oil, labor, materials, algae and culch (Table 3). Although both algae and culch are support stages in the system, they are intermediate inputs that could be produced outside the hatchery and purchased.

In most hatcheries, it is not difficult to separate the total monthly operating costs into the total cost of each primary input. The real difficulty is in allocating a share of these primary input costs to different stages of production. Im, Johnston and Langmo (1976) made some progress on such a breakdown in costs. A summary of their results is presented in Table 4. These data highlight the importance of algae production as a component in the variable costs of bivalve production and serve as a benchmark by which to calibrate the results from the bivalve cost simulation program described in the next section.

IV - SIMULATING BIVALVE PRODUCTION COSTS

This section describes a simulation model by which one may calculate input requirements, net output and the cost of growing bivalve seed. Within the model, primary input costs are allocated to different stages of production, thus facilitating the comparison of the marginal cost of growing bivalve seed to a larger size with the expected marginal revenue of doing so. The model was designed to facilitate its coding as an interactive computer program that could be used by hatchery operators.

Structure of the Model

The model can be used to calculate production costs, inputs and output for an entire batch of bivalves. Even though most hatcheries would have concurrent batches at different stages of development, focusing on a single batch makes it possible to allocate input costs to the different production stages and to generate the information necessary to determine the optimal timing of production. It is also assumed that only one production pathway is followed for each application of the model; that is, all animals in all stages are treated similarly regarding the choice of culch, timing of transfers and all other aspects of the production processes.

To compute inputs and costs for animals of different ages, each batch is initially divided into the production stages discussed above. These stages are subdivided into shorter periods so that costs can be determined at various points in time within a stage. This is particularly useful for long stages, such as the juvenile stage, where a more precise estimate of the change in cost with age is required. All periods within a

Table 4. Production Costs in Various Production Stages in Bivalve Hatcheries of Two Sizes[a]

Stage	Percentage of Total Cost		Percentage of Variable Cost

stage are of equal length, but the length and number of periods may differ amongst stages.

The number of bivalves surviving and their size are calculated at the end of each period, along with the per day averages over the period. The quantities and costs are calculated for each period and are averaged over each period as well. The costs incurred in the current period are added to those of previous periods to accumulate total costs up to the end of the period. This type of structure, in which there is a succession of repeated computations, lends itself easily to FORTRAN, the computer language in which the model is coded.[4]

As shown in Figure 7, the options to run the code are chosen in *step 1a*, and data, including price of inputs, are entered or computed in *steps 1b-1g*. After all data are entered, a batch is begun on the first day of the first month of production *(step 2)*. Each stage *i*, beginning with the conditioning stage, is looped through *steps 3-14*, and within this stage loop, period *j* is incremented *(steps 5-13)*. The passage of time during the course of a batch is accumulated within j *(step 6)*, and thus the age of the bivalves is advanced.

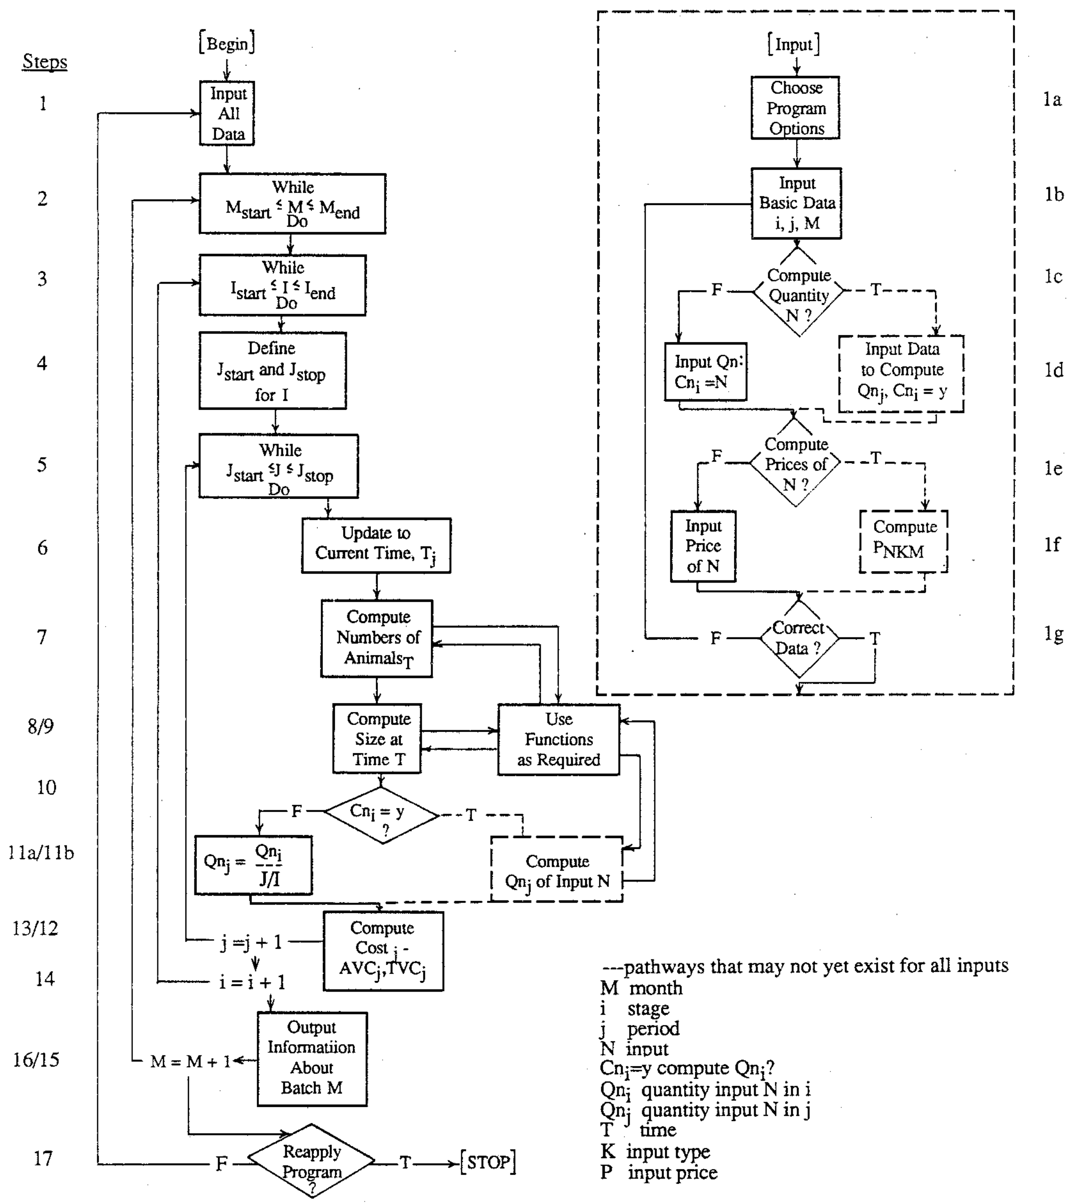
[4] Preliminary development of the code, which concentrated on specific subroutines, is shown in Myers (1985). A listing of the completed code is given in Appendix A. It is being run on an IBM mainframe computer. Data can be entered entirely by file, entirely interactively, or by a combination of both.

With this nested looping structure, any computation within the *j* loop will depend not only on *j*, but also on time, stage and the month the batch is begun.

Survival rates for bivalves *(step 7)*, size of bivalves *(step 8)* and input quantities *(step 11)* are computed within the loop j, calling function subroutines, which are placed outside of the loop when used by more than one subroutine. Cumulative and average costs, based on information from previous steps, then are computed *(step 12)*. The program output contains information generated about the batch beginning at month *M (step 15)*; a new batch is begun on the first day of month *M+1 (step 16)*. By performing computations for each month, information about batches begun at different times during the production season can be generated.

The options included in the code allow the model to be adapted to fit a variety of different hatcheries. With little effort, the internal parameters of the code can be respecified to change the number, units and name of inputs, and the number and name of stages, thus adapting the code to a hatchery's specific production methods. When running the program, the user may specify the length of each stage and the number of periods within that stage, thus determining in part the level of detail contained in the information generated. It is possible to skip entirely stages for which information is not required or for which data may be insufficient.

FIGURE 7. BIVALVE CODE FLOWCHART



The user may also choose the way in which input prices and quantities are determined. If the code contains the necessary algorithms, the user may choose either to allow the program to compute input price and/or quantities *(steps 1f, 11b)* or enter these as fixed parameters *(steps 1d,1f)*. The modular design of the code facilitates the addition or deletion of these price and quantity algorithms.

Algorithms

The algorithms for bivalve survival rates, bivalve size and production costs are required in the model and are described here.[5] In addition, the optional algorithms for algae price and quantity, which constitute the major focus of this analysis, are outlined. These algorithms, except those for price, are contained within the period loop and thus depend on time, period and stage. The prices for inputs used in a period are functions of the elapsed time up to period *j* and on the month during which that period occurs.

Survival Rate

The output from a batch of bivalves, as well as the quantity of inputs and production costs, depends on the initial number of bivalves in the batch and on the number of animals surviving from period to period. Death of a proportion of the population in a hatchery is unavoidable even though the mortality rate is lower than in the wild. Survival rates are affected by environmental conditions maintained in the tanks, but little is known about the trade-off between increasing the survival rates and cost of improving the conditions in the tanks. Survival rates will also vary by hatchery, although in all hatcheries survival should increase at an increasing rate because the animals become more resilient with age and culling rates go down with increasing age.

Hatcheries often overproduce at early stages to account for the declining numbers of animals over time, which is a result of natural mortality and the culling of inferior animals from the batch. Culling assures a faster overall growth rate and a superior final harvest. However, it is difficult to distinguish between the effects of mortality and culling on the number of remaining animals because both dead and inferior animals are removed in the same sorting process.

It is reasonable to assume that the number will decline over time. There are, however, few, if any, data on actual survival rates under these controlled conditions. At the time data were collected for this study, the hatchery had not been in production long enough to have reliable data on survival rates. For this reason, a general exponential function reflecting a constant percentage mortality rate over time was written into the code. This allows the user to specify particular survival rates and facilitates testing the sensitivity of costs to changes in survival rates.

The number surviving at the end of each period is computed at *step 7* of the code by calling a function that relates survival at time *t* to the number of animals initially in the batch, i.e., the number successfully spawned.[6] This function is:

(1) $N_t = N_o(t)^{\rho}$,

where N_t = the number of animals remaining at time *t*; N_o = initial number of animals spawned; and ρ = a parameter to be set by the user, $0 > \rho > -1$.

While this general functional relationship is thought to be an accurate representation of an invertebrate population's survival rate (Emmel, 1976, p. 205), its tendency to go to infinity as *t* goes to zero caused a problem in writing the computer code. To be consistent with the use of *t* as an index of the passage of time for other calculations, it was necessary to have equation (1) at $t=0$ record the initial number of animals in the batch (N_o) Thus for convenience of programming, N_t was defined as the number of animals remaining at the end of any week *t*, where *t* is incremented in discrete time. Thus, to reconcile the initial estimate of the number of bivalves with the continuous time function above and the other functions in the model, the following function is used:

(2) $N_t = N_o\,(t+1)^{\rho}$.

[5] The specific forms of the mathematical relationships used to describe the algorithms were chosen primarily because they were found to provide the "best" statistical results given the data used to estimate the parameters of the functions empirically. The empirical estimates are described in subsequent sections.

[6] Although the cost to condition the adult population (stage 1), which spawns the initial egg population, affects the total cost of producing a batch, the number of adults is not important in determining the initial population in this model, because N_o is input by the user as a fixed parameter rather than as a function of the fecundity of the adults spawned.

An estimate of the average number of animals surviving during a period is necessary to calculate an average quantity of inputs used during j. The actual average number over the period from time a to b is calculated by:

$$(3)\quad N_{(a,b)} = \frac{N_0}{(b-a)} \int_a^b (t+1)^{\rho}\, dt.$$

This integral was estimated in the code with a Reiman sum using the trapezoidal approximation to the area under a curve. The method gives a satisfactory estimate of the integral and increases the generalizability of the code since it does not depend on the actual form of the integrand.[7]

Size

Both the size of an individual bivalve at the end of each period and the average size during the period are estimated. This information is useful in assessing potential market price and is also necessary for computing the amount of inputs used within a period.

Data relating the size of bivalves to their age were difficult to find in the literature as well. However, Epifanio, Logan and Turk (1976) and Epifanio (1975) report a small amount of data relating the size H_t (in mm of shell height) to age in weeks (t) for both clams and oysters. These data suggest that the relationship is quadratic, at least for young bivalves:

$$(4)\quad H_t = \alpha t + \beta t^2,$$

where one would expect $\alpha \geq 0$ and $\beta < 0$, (the parameters are chosen by the user). The only potential problem with an empirical specification of this function is that it may yield a maximum size at too early an age. This problem is not serious because the function behaves well over ages that are likely to exist in a hatchery setting.

Using this relationship, the average size during any period starting at time a and ending at b is given by:

$$(5)\quad AH_{(a,b)} = \frac{1}{(b-a)} \int_a^b (\alpha t + \beta t^2)\, dt.$$

This integral also is approximated in the code using the trapezoidal rule, which computes the value of the function at each day of the period.

Costs

Estimating the variable cost to produce a single bivalve to a certain age or size involves calculating the total variable cost (TVC_t) for an entire batch at some time t and dividing by N_t, the number of animals surviving is given by:

$$(6)\quad AVC_t = TVC_t / N_t.$$

This average variable cost per animal is derived at the end of each period.[8]

As stated above, each batch is initially divided into stages $(i=1,\ldots,S)$, which are in turn divided into periods. To facilitate cod-

---

7 To estimate the definite integral $\int_a^b f(t)dt$ by the trapezoidal rule, one must calculate

$$A = \int_a^b f(t)dt \doteq \sum_{k=1}^{n-1} f(t_k)\ \Delta t + \frac{f(a) + f(b)}{2}\ \Delta t.$$

For coding purposes, it was efficient to calculate

$$A = \sum_{k=1}^{n} f(t_k)\ \Delta t + \frac{f(a) - f(b)}{2}\ \Delta t$$

and $\Delta t = 1/7$, a daily increment. If f is continuous on $a \leq t \leq b$ and twice differentiable on $a < t < b$, then there is a number $a < \epsilon < b$ such that

$$\int_a^b f(t)dt = A - \frac{(b-a)}{12}\ f''(\epsilon)\Delta t^2$$

There is no set procedure for finding the value of e such that this is true, but one can obtain some idea of the magnitude of the error by investigating the size of f"(t) between a and b (Thomas, 1960, pp. 207-17 and pp. 385-88).

8 The stage associated with the period must be greater than 1 since no animals are produced in the conditioning stage.

ing, and allow for a different number of periods in each stage, periods $(j=1,...,J)$ are indexed consecutively over the entire batch. Thus total variable costs at time t^* (measured in weeks) is the sum of all variable costs $(PTVC_j)$ across all periods included in the first t^* weeks:

$$(7)\quad TVC_{t^*} = \sum_{j \in t^*} PTVC_j.$$

Because the code keeps track of periods and stages by incrementing the *jth* loop within the *ith* loop, costs up to the end of a period may also be thought of as the sum of the costs in all periods included in the completed stages $(i=1,...,S^*-1)$ plus the sum of the costs for all completed periods up to time t^* included in the current stage, S^*,

$$(8)\quad TVC_{t^*} = \sum_{j \in (S=1,...,S^*-1)} PTVC_j \quad + \sum_{j \in (S^* \cap t \leq t^*)} PTVC_j\,.$$

Variable costs during a period are of course determined by the quantity of the inputs used during that period and by the price of the input during the month in which the input is used. This is incorporated into the model as:

$$(9)\quad PTVC_j = \sum_{n=1}^{N} \sum_{k=1}^{K} \sum_{r=1}^{R} P_{nkm_j} Q_{nkrj},$$

where P_{nkm_j} = price per unit of input n, type k, in the month during which j occurs; Q_{nkrj} = quantity of input n, type k, for use r used during j; N = number of inputs n; K = number of types k of input n; R = number of uses of input n, type k; and m_j = month during which j occurs.

<u>Prices and Quantities</u>

As discussed previously, prices and quantities are either computed by algorithms within the code or are input by the user, thus allowing the user to focus on specific parts in the production process. Although the model allows any of the input prices to be computed, this option is probably most useful in computing the cost, or internal price, of algae and culch, because these two inputs are often intermediate inputs produced within the hatchery. This analysis focuses on the computation of this internal price for algae and on the use of this input as feed during the production of the bivalves.

As shown in equation (9), the model allows for a price for K different types of input n in each month of production, thus creating a 3-dimensional price array, P_{nkm}. The code requires a value for each element of the array regardless of whether the price is computed or input by the user so that a corresponding price can be found for inputs used during any month.

From the computations for the quantity of inputs used in each period, where a quantity is calculated for each type of each input for each period, Q_{nkj}, another 3-dimensional array is constructed. Determining the quantity of each type involves summing over the R different uses for the input. For expository purposes, this is included as an additional subscript on the quantity variable in equation (9), Q_{nkrj}. However, in the code, this sum of input quantities by use is calculated in the quantity subroutine, and this subscript does not appear in the quantity array used in the cost calculations.

If the quantity of input is entered by the user rather than computed by algorithms in the code *(step 1d)*, a lump sum is entered as Q_{nki}, which is then divided equally among each period of that stage *(step 11)*.

Algae Price and Quantity

The decision to focus this report on algae production (price) and on the quantity of algae used for feed in bivalve production is justified for three reasons.

First, the production of algae in the hatchery was the most well defined and firmly established of the hatchery's production processes. It was easy to separate the inputs used in the production of algae from those used as direct inputs to bivalve production, because some different types were used and because the two processes were physically separated in the hatchery.

Second, the algae production model closely resembles the bivalve code structure because of the similarity in the production processes. By first writing the algae price code, potential problems with the full bivalve code could be anticipated.[9]

Third, and most important, is the fact that feed costs have been identified as the largest single component of hatchery costs, ranging from 29% and 33% of variable costs in early studies (Im *et al.* 1976) to as high as 85% in more recent studies (Bolton 1982). Thus, from a practical point of view,

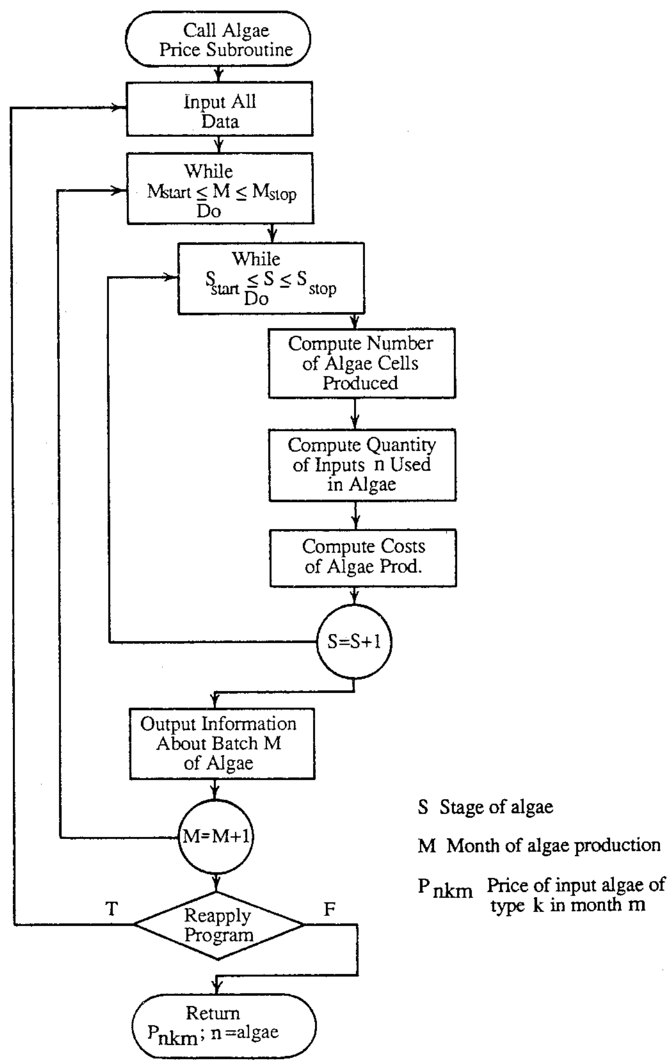
> ... the major bottleneck to commercialization of intensive bivalve culture systems [lies] in the ability to economically culture massive quantities of these suitable algal species. Intensive study of problems associated with such mass culture of algae is certainly warranted... (Epifanio 1975, p. 190).

These concerns become even more important as hatcheries attempt to raise animals to a larger size.

The algae system, described in Section *III*, can be broken into stages of relatively short, fixed duration, thus distinguishing different algae "types" by the age of the culture. Algae can be fed to the bivalves from different stages and as such provides one example of how different types of one input can be used within the code. These different types of algae are also distinguished on the basis of their different physical characteristics, such as density, and overall purity, and by the cost of production. In the subroutine where algae costs are computed, a price, which in this case equals production costs, is computed for each of the different algae types.

Figure 8 is a representation of the algorithms used to simulate algae production. As in the bivalve program, only one batch of algae is followed at a time. It is also assumed that only one algae species, or a single mixture of species, is produced in a batch and that all tanks within a stage are used. By assuming that a new batch is begun on the first

FIGURE 8. ALGAE PRICE SUBROUTINE



[9] In fact, the two processes are very similar inasmuch as both operate on a batch-like principle. The transfer of algae to successively larger tanks as they mature is comparable to the transfer of animals between stages. Both systems are a function of the number of animals or cells; however, the number of organisms increases over time in the algae system due to cell reproduction, although cell size remains constant.

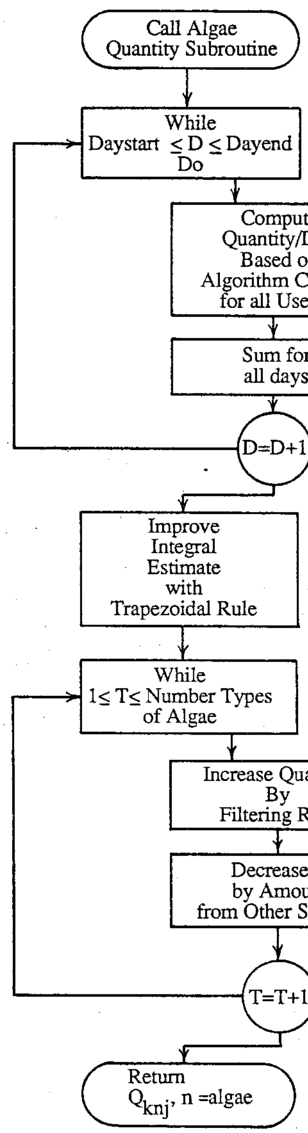
of every month, one can derive the 3-dimensional price array required by the bivalve program, P_{nkm_j} from equation (9) (where n = algae), from the internal cost of producing each type of algae.

The cost of producing any stage of algae depends on the amount of inputs --electricity, labor and materials-- used during the stage and on the price of those inputs during the month in which the stage occurs. Because algae production in the hatchery is separate from bivalve production, there is a provision in the data input to specify different prices for those inputs used in producing algae from those used in other parts of bivalve production. The algorithms used to derive the internal costs of producing algae are discussed in detail in Myers (1985).

The algae quantity subprogram is used to compute the feed requirements for a batch of bivalves at any time t (see Figure 9). It allows for the feeding of algae from any stage of maturity to bivalves at any stage of growth, although it is likely that average production costs per unit of algae would be too high in the early stages. Exactly at what stage during the algae production process algae should start to be used for feed is an empirical question that can only be answered by the information generated from the program itself. More is said about this issue below.

To estimate the algae required for a batch of bivalves, one must know the relationship between feed consumption and some measure of a bivalve's age or size, in addition to the number of animals remaining in the batch at time t. In the literature, one finds feed requirements related directly to age (Epifanio 1975) and directly to size, as measured by shell height or dry weight (Epifanio *et al.* 1975 and Bolton 1982). To maintain the flexibility of the program, both options were included in the code. This was accommodated easily, because regardless of the relationship used --size and feed or age and feed-- the data are consistent with a function that is linear in logarithms. One might well interpret the relationship as a Cobb-Douglas production function.

FIGURE 9. ALGAE QUANTITY SUBROUTINE



In the first option contained in the code, the daily consumption of algae (10,000 cell units) at time t, C_t, is related to shell size in mm of shell height as determined from equation (4). Thus,

(10) $ln(H_t) = \delta + \gamma \; ln \; C_t.$

Solving for C_t and substituting,

(11) $C_t = (e)^{-(\delta/\gamma)} (H_t)^{1/\gamma}.$

Multiplying this expression by the number of animals surviving (N_t) and substituting from equations (7) and (9), the total daily feed requirements (in 10,000 cell units) for a batch at time t, C_t^* can be written entirely in terms of t:

$$(12)\quad C_t^* = [(\alpha t + \beta t^2)^{1/\gamma}]\,[(t+1)^{\rho}\,N_0]\,[e^{-\delta/\gamma}].$$

The total number of algae cells consumed (in 10,000 cell units) during a period is then given by

$$(13)\quad \overline{C_t} = e^{-\delta/\gamma}\int_a^b [\alpha t + \beta t^2]^{1/\gamma}[(t+1)^{\rho}]dt.$$

Again, the values of the parameters are left to the user.

The second option relates the cells consumed, c_t, directly to age in weeks, thereby eliminating the need to evaluate equation (4). The new relationship is[10]

$$(14)\quad \ln t = \xi + \eta \ln c_t.$$

Thus,

$$(15)\quad c_t = (e)^{-(\xi/\eta)}\, t^{1/\eta};$$

$$(16)\quad c_t^* = [t^{1/\eta}]\,[(t+1)^{\rho}\;N_0\,]\,[e^{-\xi/\eta}];$$

and

$$(17)\quad \overline{c_t} = e^{-\xi/\eta}\int_a^b [t^{1/\eta}\,]\,[(t+1)^{\rho}\,N_0\,]dt.$$

Both of these options create the 2-dimensional array for algae quantity.[11] The price determined in the algae price routines can then be referenced to compute the cost of the algae inputs used in each period of bivalve production.

10 The variables C_t and c_t refer to feed consumption (in 10,000 cell units), calculated according to options 1 and 2, respectively.

11 Both equations (13) and (17) are evaluated in the program using procedures similar to those for the survival and size equations above and reference equations (2) and (4) for each day of the period.

V - EMPIRICAL TESTS OF THE SIMULATION MODEL

The purpose of this section is to describe the results from initial experimentation with the bivalve cost simulation model. The decision to apply the model to oyster seed production (*Crassotrea virginica*) was based primarily on the availability of data. As emphasized above, the empirical results reported here focus on simulating the cost, or internal price, of algae and on the quantities of algae and total feed costs of raising a batch of bivalves to various sizes. The remainder of this section begins with a discussion of the data used for the analysis. Next, the empirical results are presented for a base case, after which a variety of sensitivity analyses are conducted to see how the empirical results are affected by changes in the key parameters of the model.[12] Finally, these results are compared with other cost and bivalve seed price information to provide initial indications of the optimum size at which to market the seed.

The Data

To experiment with the model, it was necessary to obtain two sets of information: a) the data required by the subprogram that calculates the cost or internal price of algae and b) data by which to estimate the parameters of the survival function, the age-size relationships and the algae feed functions [equations (1), (4), (10) and (14)]. The data for the algae price (internal cost) estimates are based in large measure on several weeks of observation at the hatchery during the summer of 1983. There were, however, a few items taken from other sources, but these were modified to be consistent with the other production processes and specific environmental conditions of the hatchery. These data are summarized in Appendix B and are described in detail by Myers (1985).

For any single type of bivalve, there were very few data in the literature on which to base the estimates of the parameters for

12 Myers (1985) conducts considerable sensitivity analysis on the internal price of algae, so these results focus on changes in other parameters of the system.

equations (1), (4), (10) and (14). However, except for the survival equation, it was possible to combine data from several sources to derive consistent parameter estimates for the oyster.

Table 5 contains an empirical estimate of equation (4a), relating the size of oysters to age. The data are from Epifanio *et al.* (1976).

Within the simulation model, there are two alternatives for estimating the feed (algae) requirements for bivalves. One way is to relate feed directly to shell height as in equations (10a,b) of Table 5. To estimate equation (10a), equation (4a) was used first to predict shell height at some selected ages for which Claus and Adler (1970) report algae consumption data. These predicted shell heights are then regressed on the algae consumption figures (in log-linear form) to obtain equation (10a). Equation (10b) was estimated directly from data in Bolton (1982). A second way to estimate feed requirements accommodated in the model was to relate algae consumption directly to age. Data from Claus and Adler (1970) were used to estimate equation (14a) directly, while equation (14b) was estimated directly from information in Bolton (1982).[13]

The primary reason for developing these four ways of estimating feed requirements was to test the sensitivity of the model. It is somewhat surprising, but encouraging, to find that the algae production elasticities in these four equations are similar, ranging only from 0.35 to 0.42.

Data with which to estimate the survival rate parameters were among the most difficult to obtain. There were no population survival data for oysters raised in a hatchery, although Bolton (1982) makes allowance for a 20% mortality rate during the cultivation period. Because most assumptions in Bolton's experiment proved extremely optimistic, it seemed inadvisable to use this overall mortal-

[a] See text for equation numbers and variable definitions. The numbers in parentheses and brackets are t-ratios and standard errors, respectively.

[b] The source of the data is Eldridge, et al. (1979).

[c] R^2's are not applicable for restricted regressions.

[d] The source of the data is Epifanio et al. (1976).

[e] The source of the data is Bolton (1982).

[f] The sources of data are Claus and Adler (1970) and Epifanio et al. (1976).

[13] Bolton (1982) estimates oyster feed requirements through a mathematical relationship between the whole weight of oysters and the daily consumption of algae (due to Pruder et al. (1977)):

$$Y = 8.2\ x^{-0.21}$$

where x = whole weight in grams; and Y = algal cells cleared x 10^8/g whole weight/day. Because they report data on age and shell height for oysters of different whole weights, once this equation is used to estimate algal consumption based on weight, these predicted values can in turn be regressed on age and shell height to obtain equations (10b) and (14b).

ity rate as a base of comparison. Furthermore, there was no easy way to infer from this overall rate how mortality changes over time.

Since hatchery data on which to estimate survival rates of oysters or other bivalves were unavailable, the best alternative to obtain survival rates that are at least in the relevant range was to estimate equation (1) from data for hard clams planted in protective trays in a South Carolina estuary (Eldridge *et al.* 1979). The size of the clams planted was larger than bivalves raised in a hatchery, and the survival function for smaller bivalves had to be extrapolated beyond the limits of the data. Initially, one might except this to lead to an overestimate of the survival of hatchery-sized bivalves. However, the data do reflect a less controlled environment than found in the hatchery, a factor that may partially offset the effect of size. The estimated equation, in log-linear form, is in Table 5; its parameters imply a constant mortality rate of 25.5%. When accumulated on a weekly basis, this function leads to over 60% mortality in a year's time, three times that for oysters in Bolton's (1982) prototype hatchery. This discrepancy is large, but it is unlikely that Bolton anticipated a year-long cultivation period. Equation (1a) from Table 5 implies about a 50% mortality after 18 weeks. This is closer to Bolton's initial assumptions. These two extremes are a useful range over which to test the sensitivity of the results.

Empirical Results

A computer program was designed that implements the simulation model described in detail above. This program was designed to be used by the hatchery operator to generate information about a batch of bivalves at different states of development. Input costs and requirements, and bivalve age, survival and size are reported at the end of each production period and as cumulative amounts. Most important, it gives an average cost per bivalve at the end of each period to give the user information about production timing and about the expected revenue from bivalve seed sale that might be expected.

Initial Simulations

A partial listing of the printout generated by the program is in Appendix B. It contains information for a batch of oysters under base run conditions (run 1). The batch is assumed to begin in April and last for 420 days, or 59 periods. Myers' (1985) input and price data were used to calculate the internal cost per unit of algae.[14] The data reflect economic conditions at the hatchery in 1983. The batch contains one million oysters initially; the survival rate for bivalves is given by equation (1a), of Table 5; the age-size and feed-size relationships are given by equations (4) and (10a), respectively. The bivalve feeding filtering rate is assumed to be 50%, and 12% of the diet is assumed to come from algae in circulating sea water in the juvenile stage.

The assumptions underlying the base run and 11 other simulations are given in Table 6. These runs contain numerous combinations of the functional relationships described earlier in Table 5. The first three runs assume the same mortality rates but accommodate different ways of estimating the physical feed requirements. Runs 1 and 3 assume feed is directly related to size, although in run 2, feed is directly related to age. The results of these runs are summarized in Table 7.

For the base run, the number of bivalves surviving over the duration of the batch falls from a million at spawning to an estimated 938,000 at the beginning of the larval stage. After setting, the estimated number is 716,000. If the batch were to remain in the hatchery for 420 days (including 60 days for conditioning the broodstock), the

---

14 To facilitate comparisons, all other runs of the model are assumed to begin in April and run for 59 periods (420 days). The simulation was run over such a long duration primarily to test the behavior of the model since, due to bivalve size and the cost of feed, it is clear that bivalve seed would be sold or transferred to grow-out long before this last period was reached. Conditioning takes a month, and the spawning, larvae and setting stages were broken into periods of a few days each; but once the juvenile stage was reached, periods were a constant one week in length. For ease of exposition, much of the discussion in the text focuses on monthly intervals or on individual stages.

[a] See Table 5 and equations (1), (4), (10) and (15) in the text for parameter definitions and estimated relationships.

number of animals surviving would be approximately 357,000.

The estimated average size of the bivalves ranges from just under 2 mm after the setting stage to just over 33 mm at the end of the simulation. As the batch progresses through time, the additional cost of feeding larger bivalves is partially offset by declining numbers. Because the feed cost per surviving bivalve includes the accumulated costs of feeding those that did not survive, the costs rise rather rapidly throughout the batch. At the end of period 18 (about 100 days), the feed cost per animal is still less than one cent, but if left in the hatchery through the 59th period, feed costs would average more than a dollar per surviving bivalve.

Table 7. Summary of Simulation Output for Initial Runs

Period[a]	Stage	Cumulative Days to End of Period	Animals Surviving (thousands)	Average Size of Animal (mm)	Cumulative Cost per Bivalve: Run 1[b] (Base) ($)	Run 2 (Proportion of Run 1)	Run 3 (Proportion of Run 1)

[a]Period 6 is through setting (about 50 days including adult conditioning, spawning and larval stages); the remaining periods are a week in length.

[b]See Table 6 for assumptions about runs.

[c]Less than 0.001.

Data for the other runs in Table 7 suggest that these results can be quite sensitive to the assumptions made regarding the feed equations. In the base run, feed requirements are related directly to the size of the animal, whereas in run 2 it is assumed that feed requirements are determined by equation (14a) relating feed directly to age. Assuming the same survival rates, this alternative way of calculating feed leads to a slightly lower estimate of feed cost per surviving animal through period 18, but then cost rises to 1.3 times that of the base run by period 59. The feed relationships in these two runs were estimated from the same basic data; despite these differences, the results are quite consistent.

The cumulative costs from run 3 are in sharp contrast to those for runs 1 and 2. In this latter run, costs are consistently higher than in the base case, and within the same run the differential is most extreme in the early periods. This result is somewhat surprising, given that the production elasticity for algae is higher in runs 3, 4 and 6 than in the base run. However, the intercepts on the size or age axes of the production function are lower than for the base run. Thus, even though the percentage gain in size is larger for each one-percent change in algae consumption, absolute feed requirements to raise these oysters to any size over the duration of the batch remains higher than in the base run.

The implications of this result lie in the importance of measuring feed requirements accurately in early stages of the growth process. That is, if one were to look only at a single animal, the tendency would be to conclude that feed costs would be relatively unimportant compared to costs for older animals. However, because the number of animals falls throughout the process, costs (due to what appear to be minor cost differences in early periods) accumulate rapidly as more animals die and as total costs are averaged over fewer survivors. Thus, reliabile estimates for both feed costs at different points in the growth process and the number of animals surviving are more critical in estimating costs for raising bivalves than for larger animals (e.g., cattle or other livestock) with much lower mortality rates.

A Digression on Algae Production

The primary focus of the analysis so far has been on the costs of feeding a batch of bivalves and the effect of survival and feeding ratios on costs. However, it is evident (Table 8) that cumulative algae consumption in runs 2 and 3 is a smaller multiple of the base run consumption than it is for cost in early periods and is a larger multiple in later periods. The primary reason for this is that feed costs for bivalves are also a function of the implicit price or cost of algae that is raised for feed. The program uses algorithms from Myers (1985) to calculate the price of algae, which are assumed to be constant in any month but which can vary by month because of seasonal differences.

The "algae price" algorithm assumes that algae are produced in a batch process, which is divided into 6 stages covering about 6 to 7 weeks. During the first four stages, most of the algae are needed to innoculate the subsequent stage. Thus, the net production of algae available is negligible until the tertiary stage (about 6 weeks). Up to this point the algae are grown in well water and the batch is quite pure, thus making it ideal for feeding to bivalves at the larval and set stages. These tertiary algae tanks are located (in the study's hatchery) adjacent to the larval tanks, which

Table 8. Algae Consumption for Selected Simulations

[c]Ratio of column 7 (Table 7) to column 3 (Table 8) and column 8 (Table 7) to column 4 (Table 8), respectively.

helps keep the costs of moving algae around the hatchery to a minimum. There are an estimated 9,650 litres of algae available at the tertiary stage, most of which is fed to the larvae and animals at set. Some of the tertiary algae is also used to innoculate a solar stage to which seawater, rather than well water, has been added, thus making it unusable for the sensitive larvae. After another week or two, there are an estimated 67,000 litres of algae available to feed juvenile bivalves. Because the cost per cell of algae in the solar stage is about 25% of that in the tertiary stage, it is not surprising that in the early periods feed cost is higher relative to algae consumption than it is in later periods (Table 8).

A further explanation for the behavior of costs relative to algae consumption lies in a slightly higher algae cost estimate in the summer months because of the air conditioning required to maintain cool temperatures suitable for algae production. For example, assuming the batch is started in April, about 82% of the cost of algae in the solar stage is due to labor, 5% to materials and 13% to electricity, much of which is used for cooling. Thus, as the bivalve production moves into autumn, cooling requirements are reduced and production costs fall by as much as 3% relative to a batch available in July.

Implications of Different Survival Rates

The accuracy of hatchery cost estimates derived by this analysis depends on the number of animals surviving at any stage. To test the sensitivity of these results, the survival parameter was changed by plus and minus one and two standard derivatives from the least squares estimate of equation (1). A decrease in the absolute value of the parameter, as in runs 4 and 6, implies a lower mortality rate, whereas an increase in its absolute value leads to higher mortality (runs 5 and 7).

The results of these sensitivity tests are summarized in Table 9. The change in

Table 9. Summary of Simulations to Test Sensitivity of Survival Parameter

[a]See Table 7 for explanation of periods.

[b]See Table 6 for assumptions about runs.

the number of surviving bivalves is predictable directly from the parameter changes. Because of the form of the survival function, mortality is assumed to occur at a compound rate. Thus, for increases in mortality, the proportion of bivalves surviving, relative to changes in the base run, falls as the batch moves to later stages. Total feed costs (relative to the base run) fall as well, but not quite so fast. Exactly the opposite is true when mortality rates are reduced.

Perhaps the most important result from this analysis is that despite significant differences in the number of surviving animals (from 0.72 to 1.5 times the base run), cumulative costs per bivalve are never any more than plus or minus 3% of the base run costs. The important implication of this result for hatchery owners is that relatively accurate estimates of per-unit variable costs can be made somewhat independently of good estimates of survival. This is critical in comparing per-unit costs to the potential price of seed to determine when to sell.

Sensitivity of the Relationship of Age and Feed to Size

Although the average cost per bivalve is relatively insensitive to the assumptions made about survival rates, the results of the initial simulations suggest that this is not the case for the relationships between age and size and between feed and size. The importance of these relationships is perhaps best understood by systematically changing the parameters of equations (4) and (10a), assuming the other assumptions in run 1 are constant. The results of this experimentation are summarized in Table 10.

To begin the analysis, the coefficient on the linear term was changed by plus and minus one and two standard deviations. It was readily apparent that although the change

[a]See Table 7 for explanation of periods.

[b]See Table 6 for assumptions about runs.

[c]Total feed costs as a proportion of those in run 1 are the same as the feed costs per bivalve.

in feed costs was more dramatic than the change in bivalve size, both remained about proportional to the change in the parameter, α. Thus, only one of these runs, where α is reduced by two standard deviations, is reported (run 8). This change reduced the estimated size by about 90% of the base run size while reducing feed costs to between 72 to 76% of base run costs.

The next step in the analysis was to change the coefficient on the t^2 term in equation (4). In run 9, the coefficient on the linear term was the same as in run 11, but the absolute value of the coefficient on the squared term was increased by two standard deviations. The effect of this change on both size and feed costs was minimal in the early stages that would be most relevant to a hatchery producing seed to be sold or transferred to growout facilities. At later stages, the effect of this parameter change becomes increasingly important.

The most significant results from Table 10, however, seem to be the large reductions in feed costs due to an increase in the production elasticity of algae in equation (10a). By raising the production elasticity to one standard deviation above its original level, costs fall to just under 60% of the base run (run 10) in period 6 and to 13% by the end of the simulation. Increasing the production elasticity by an additional one standard deviation leads to further, but not quite so dramatic, cost reductions (run 11).

Preliminary Observations about Total Costs of Production

Because data were unavailable from the hatchery on other aspects of the production of oyster seed, it was impossible to implement all parts of the simulation model and estimate costs other than feed costs. However, at least two previous studies contain estimates of the proportion of total costs accounted for by algae feed. On the basis of these estimates, it is possible to make some preliminary observations about total production costs and thus about when during the batch costs will exceed the price that a hatchery operator might receive for the seed.

As reported in Table 4, Im *et al.* (1976) estimate that algae feed costs are about one-third of total production costs; Bolton (1982) reports estimates ranging from 15 to 85% of total costs. Feed costs, as a percentage of total costs, probably increase with age. However, the nature of this relationship is not known; so to obtain some idea of what this wide range in estimates implies for the simulation results above, two kinds of sensitivity analysis were conducted. The first was to assume that feed costs are a constant fraction of total costs (first three panels of Table 11). By assuming feed costs are 33, 59 and 85% of total costs, one is able to reflect all but the low range of Bolton's estimates. It was believed that this low end of the range would apply only to very young bivalves. To reflect increasing relative feed costs, the last two panels in the table assume that costs rise linearly from 15 to 85% of feed costs from period 1 through 59 and period 1 through 30, respectively.

These sensitivity results have important implications for marketing bivalve seed in that Matthiessen and Smith (1979) argued that oyster seed (2 to 3 mm in size) could be purchased at from $2.00 to $5.00 per thousand. Assuming these prices, base run conditions and feed costs at 33% of total, seed would have to be sold prior to the 11th period (5.5 mm shell height) to cover costs if the price were $2.00 per thousand, and before the 13th period (6.9 mm shell height) if the price were to be $5.00 per thousand. This "window of opportunity" would occur much earlier (periods 5 and 6) under the most costly conditions (run 3), but only slightly later (periods 14 and 17) for the least cost scenario (run 10).[15]

These results are remarkably consistent, given the wide range of parameters in the age-size and size-feed relationship reflected in these runs. The "marketing win-

---

15 Since this is a "batch process" and per bivalve feed costs are relatively insensitive to survival rates, it's unlikely that these marketing opportunities would change much if different survival rates were assumed. This does not mean, however, that survival rates are unimportant in terms of the overall profitability of the batch.

[a]See Table 7 for explanation of periods.

[b]See Table 6 for assumptions about runs.

[c]These are the percentages that feed costs are assumed to be of total cost. In the last two panels, costs are assumed to increase linearly from 15 to 85% of feed cost from periods 1 through 30 and periods 1 through 59, respectively.

[d]Less than 0.0005.

[e]Actual period during which costs reach $0.002, $0.005 and $0.010, respectively, per bivalve.

dow" is extended by only 2 or 3 weeks if feed costs actually turn out to be 85% rather than 33% of total production costs or if feed costs are assumed to rise to 85% of total costs over 30 rather than 59 periods. A doubling of the price (from $0.005 to $0.01 would extend the marketing period by only an additional 2 to 3 weeks as well.[16]

It is also important to recognize that during these "break-even" marketing periods, it is estimated that the size of the seed is much larger than the 2 to 3 mm on which the prices are based. This implies that the hatchery owners may be in an advantageous bargaining position to sell seed that meets the size requirements earlier, thus reducing costs, or by asking for a higher price for larger seed, with its higher survival rates during growout.

VI - SUMMARY AND CONCLUSIONS

The bivalve aquacultural industry in the northeastern United States has been strengthened in recent years by declining and fluctuating natural harvests in the surrounding coastal region. The hatchery industry, in which the bivalves are grown only to a small seed size, has gained acceptance as an important link in the aquacultural process; the firms in the industry are potentially able to provide a consistent, reliable source of seed with which the bivalve aquaculturist begins the production process. They have also gained acceptance as a seed supplier to local governments, who artificially seed depleted natural bivalve beds with the seed purchased from hatcheries. Hatcheries as an industry are likely to play a larger role in the overall production of bivalves if they can overcome some of the technical and economic problems with which they must contend.

The techniques involved in the production of bivalve seed in hatcheries have evolved only recently, yet are technically sophisticated compared to other open-water aquacultural techniques. The production processes differ, but each requires a precise sequence of steps under carefully-controlled and -monitored environmental conditions. Mature adult clams or oysters taken from hatchery-maintained broodstock are induced to spawn. The gametes are transferred into large, conical larvae tanks where they freely circulate in warm, algae-rich seawater. The concentrated algae used for feed are grown in the hatchery or taken from seawater. After several weeks, the bivalves undergo a metamorphosis where they change from free-swimming larvae to bottom-dwelling spat. Prior to this time, the animals are transferred to set tanks where they are induced to attach to culch -- a material purchased or produced in the hatchery generally from crushed bivalve shell. Once the animals have passed through the delicate setting period, they are transferred to the juvenile tanks where they can be exposed to large quantities of algae and seawater. The animals remain in these tanks until they reach a suitable size for transfer to open-waters.

There are a number of production options available to the hatcherist, the most apparent being the design of the production system and the source of inputs. The algae production method is the greatest cause of variations affecting cost among hatcheries. These methods include the centrifuging of algae cells from seawater, continuous culture methods, or a batch process in which production is separated into distinct stages. The type of culch used and the number of animals produced as culched or culchless (attached or non-attached to the culch) also differ among hatcheries. The hatcherist has a great deal of discretion regarding the optimum survival rate of the animals in relation to the quantity and quality of inputs used. Finally, and most central to this research, is the choice of when to sell seed.

Despite the growth of the industry and advancements in the technical processes of hatcheries, little is known about the economics of the hatchery. There have been several important studies on this aspect of hatcheries (Im, *et al.*, 1976 and by Im and Langmo, 1977). These and other studies fail to pay sufficient attention to the wide variation that exists among hatcheries and to break

---

[16] This price was included because there has undoubtedly been an increase in the price of seed between that reported by Matthiessen and Smith (1979) and 1982, the year for which the algae cost data apply.

cost down by period of the animal's life. Estimates of cost by period are essential to determine the optimal time (*viz.* size) at which to sell the seed, inasmuch as the optimal selling age is at the point where marginal cost is equal to the price that could potentially be received.

The purpose of this research is to contribute to the existing body of knowledge about the hatchery industry by examining the factors that influence production costs. The research is partly based on observations of a working hatchery located in the northeast and on current literature, with particular attention paid to the variations that exist among hatcheries. The data collected were used to develop the framework for a computer program that could estimate variable production costs. The program routine was intended to enable the individual hatcherist to determine the optimal size at which to sell the bivalve seed.

Creation of this program required the development of an algorithm that simulates the production process. The model sums costs at different stages of animal growth, which are further broken down into smaller units of time. In this way a cost can be computed at any given point in the animals' lives. The cost incurred during any given period of time is a function of the quantity of inputs used and their prices. Thus, the major component of the model was designed to determine the quantity of inputs used and the cost incurred during any given period.

There was sufficient information available from the literature and hatchery observations to simulate the overall production system. Unfortunately, records concerning the expenditures did not distinguish between hatchery and open-water field operations nor did they break costs down by stage. Consequently, data were not available to allow for all aspects of the model to be completed in detail. Data on the batch algae production process used by the hatchery were, however, more readily isolated from the rest of the hatchery because of the physical separation of the two systems in the hatchery. Thus, the focus of the empirical analysis was on the estimation of costs of algae production and is justified since feeding costs are recognized as a large proportion of total costs.

The FORTRAN computer program that is based on the model focuses on the cost of producing algae feed, but as more details become available about other hatchery production processes it would be a simple matter to incorporate them into the existing FORTRAN code. The computer program calculates the cost, or internal price of algae to the hatchery, and then combines this information with survival and growth rates and feeding efficiencies to determine total (and per unit) feeding costs to raise a batch of bivalves to various sizes. The algorithms are used to examine the sensitivity of the algae production parameters and to the parameters of the bivalve growth, survival and feeding relationships.

The model is applied to raising Atlantic Oyster seed, using data on algae production from the hatchery and data on survival rates, feeding efficiency and growth rates available from the literature. Twelve initial simulations were made. The output from each contained a summary of input prices and requirements and costs for bivalves at different periods throughout the production process, along with the age, size and number of bivalves and the total and average costs per bivalve.

The 12 simulations reflect a range of assumptions about survival rates, growth rates and algae feeding rates. In the base run, feed requirements are related directly to animal size. The feed cost per surviving bivalve remains less than one cent up to 100 days but rises rapidly thereafter. In a second run, based on the same data to relate feed directly to age, feed cost remains lower for the first 100 days, but then rises to 1.3 times the base run.

As might be expected, the feed costs per bivalve are extremely sensitive to the parameters of the feeding relationships and to the age-size relationship. This is not particularly encouraging because there seem to be few sources of data in the literature from which to estimate these relationships. The one encouraging thing is that feed costs are less sensitive to these parameters for very young bivalves than for older ones, and it is the young bivalve that is of most interest to a hatchery. Another important result is that for wide differences in the numbers of animals surviving, the feed cost per surviving animal (including the accumulated cost of feeding those that did not survive) varied by no more than plus or minus 3%. Having good estimates of feed costs per animal in the face of considerable uncertainty about survival rates may well facilitate planning when to sell the bivalve seed or transfer them for growout.

To explore the implications of these feed cost simulations for the marketing of bivalve seed, some rough estimates of total costs of production per bivalve were developed on the basis of others' estimates of the proportion that feed costs are of total costs. Total costs were estimated for several simulations assuming feed costs were 1) one-third, 2) nearly 60%, 3) 85% of total costs, and 4) a linear function of total costs starting at 15% and rising to 85% by the end of the production period. While the time period at which price just covered costs differed significantly over the scenarios, within a given scenario the "break-even" marketing periods varied only by a week or two in spite of diverse assumptions about the fraction feed costs are of total costs.

In conclusion, this research demonstrates that it is possible and practical to estimate algae and feeding costs for a seed producing bivalve hatchery using a computer program to simulate the production system. The most optimistic assumptions suggest that bivalve seed can be produced and marketed profitably. These conclusions must be qualified by the fact that sufficient data were not available from the hatchery under study to estimate all components of total cost. Collection of these types of data would help in further testing of the algorithm as well as contributing to an overall understanding of hatchery costs at each stage of production. Equally important from a research perspective is the need for better data on hatchery survival rates and the size-age and feeding rates. What data do exist in the literature on which to estimate these rates lead to quite different implications for feed costs, and none of the existing data sets contains more than a few observations. Thus, in the absence of more extensive research data on which to estimate these important physical relationships, anyone attempting to use this kind of software for management decisions is well advised to use information that is specific to a particular hatchery.

C  VARIABLES DO NOT CHANGE WHEN ORGANISM CHANGES

C  STRUCTURE:  GENERAL PROGRAM INFORMATION
C              OPTION TO CALL SUBR. INFORM TO DISPLAY PROGRAM INFOR.
C              CALLS SUBR. READIN TO READ IN ALL DATA
C              CALLS SUBR. BODY TO DO COMPUTATIONS
C              OFFERS OPTION TO RERUN PROGRAM WITH MINOR CHANGES

C??????????????????????????????????????????????????????????????????????
C  GENERAL PROGRAM INFORMATION:
C  ---------------------------

C  TITLE :  ORGANISM COST SIMULATION MODEL
C  AUTHOR:  JULIA A. MYERS
C  PLACE :  CORNELL UNIVERSITY
C  DATE  :  DECEMBER 6, 1986

C  LANGUAGE: FORTRAN FF  - IBM COMPATIBLE
C            NONSTANDARD - MIXED CHARACTER COMMON BLOCKS, INCLUDE,
C                          '$' IN VARIABLE NAMES
C  DOCUMENTATION: USER SPREAD-SHEET (FOR INPUTTING DATA)

C     THIS INTERACTIVE FORTRAN PROGRAM CONTAINS THE BASIC STRUCTURE
C  OF A MODEL NECESSARY TO SIMULATE THE COST OF PRODUCING
C  ANY ORGANISM THAT GROWS BY STAGES. THE COST AND QUANTITY OF INPUTS
C  IS DETERMINED AT EACH STAGE OF THE ORGANISMS' LIVES AND AT
C  DIFFERENT PERIODS IN THOSE STAGES.
C     THE PROGRAM'S MODULAR DESIGN ALLOWS SUBROUTINES TO BE ADDED
C  FOR SPECIFIC INPUTS AND STAGES OF THE PRODUCTION PROCESS
C  THEREFORE, IT IS POSSIBLE TO DETERMINE ALL OR ONLY PART OF THE TOTAL
C  COST OF PRODUCTION.  EACH SUBROUTINE CONTAINS A DESCRIPTION OF
C  THE PROGRAM VARIABLES THAT MUST BE RETURNED TO THE PROGRAM.
C     THE CURRENT CAPABILITIES OF THE PROGRAM ARE INITIALIZED IN BLOCK
C  DATA, BLK1.  THESE MUST BE RESET WHEN SUBROUTINES ARE ADDED OR
C  DELETED.  SEE THE ACCOMPANYING PROGRAM DOCUMENTATION.
C     THE PROGRAM WAS TESTED FOR THE PRODUCTION OF BIVALVE SEED IN AN
C  ENCLOSED HATCHERY.  THUS, SOME SUBROUTINES ARE SPECIFIC TO
C  THIS ORGANISM AND THE APPROPRIATE CHANGES MUST BE MADE FOR OTHERS.

C  NAME    DESCRIPTION OF REQUIRED ASSOCIATED FILES INCLUDED IN PROGRAM
C  ------  ------------------------------------------------------------
C  IPAR1   PARAMETERS NECESSARY FOR GENERAL COMMON BLOCK VARIABLES
C  ICMAIN  VARIABLES IN COMMON NECESSARY TO RUN GENERAL PROGRAM
C  ICUNIT  VAR. IN COMMON FOR UNIT NUMBERS OF READ AND WRITE
C  ICBLK1  VAR. IN COMMON USED IN SUBR. BLOCK DATA BLK1
C  ICBLKO  VAR. IN COMMON, USED IN SUBR. BLOCK DATA BLK1 FOR ORG.
C  ICORG   VAR. IN COMMON SPECIFIC TO ORGANISM
C  (NOTE:  OTHER FILES MAY BE REQUIRED FOR ORGANISM SPECIFIC ROUTINES)
C----------------------------------------------------------------------

C----------------------------------------------------------------------

C  NAME    DESCRIPTION OF REQUIRED SUBROUTINES AND FUNCTIONS BY APPEARAN
C  ------  ------------------------------------------------------------
C  ORGNSM  MAIN PROGRAM
C  INFORM  READS OUT INFORMATION CONCERNING THE PROGRAM
C  READIN  READS IN OPTION INFO AND CALLS ALL SUBROUTINES TO READ IN
C  ROUT    READS OUT DATA FROM READIN
C  READS   READS IN DATA TO RUN GENERAL PROGRAM
C  ROUTS   READS OUT DATA FROM READS
C  READO   READS IN DATA SPECIFIC TO ORGANISM
C  ROUTO   READS OUT DATA FROM READO
C  READN1  READS IN DATA TO COMPUTE QUANT OF INPUT 1
C  READN2  READS IN DATA TO COMPUTE QUANT OF INPUT 2
C  READN3  READS IN DATA TO COMPUTE QUANT OF INPUT 3
C  READN4  READS IN DATA TO COMPUTE QUANT OF INPUT 4
C  READN5  READS IN DATA TO COMPUTE QUANT OF INPUT 5
C  READN6  READS IN DATA TO COMPUTE QUANT OF INPUT 6
C  ROUTN1  READS OUT DATA ENTERED IN READN1
C  ROUTN2  READS OUT DATA ENTERED IN READN2
C  ROUTN3  READS OUT DATA ENTERED IN READN3
C  ROUTN4  READS OUT DATA ENTERED IN READN4
C  ROUTN5  READS OUT DATA ENTERED IN READN5
C  ROUTN6  READS OUT DATA ENTERED IN READN6
C  PRICE1  COMPUTES PRICE OF INPUT 1
C  PRICE2  COMPUTES PRICE OF INPUT 2
C  PRICE3  COMPUTES PRICE OF INPUT 3
C  PRICE4  COMPUTES PRICE OF INPUT 4
C  PRICE5  COMPUTES PRICE OF INPUT 5
C  PRICE6  COMPUTES PRICE OF INPUT 6
C  BODY    LOOPS THRU EACH MONTH TO CALL $ AND QUANT SUBR.
C  NUMBRB  COMPUTES NUMBER OF ORGANISM AT PERIOD,J
C  SIZE    COMPUTES SIZE OF ORGANISM AT PERIOD J
C  QUANT1  COMPUTES QUANT OF INPUT 1 USED IN J
C  QUANT2  COMPUTES QUANT OF INPUT 2 USED IN J
```

```
C  QUANT3   COMPUTES QUANT OF INPUT 3 USED IN J
C  QUANT4   COMPUTES QUANT OF INPUT 4 USED IN J
C  QUANT5   COMPUTES QUANT OF INPUT 5 USED IN J
C  QUANT6   COMPUTES QUANT OF INPUT 6 USED IN J
C  COSTJ    SUMS AND COMPUTES COST OF INPUTS IN PERIOD, J
C  WRTOUT   PRINTS COSTS AND QUANTITIES
C  WOUTN1   PRINTS ADDITIONAL INFO GENERATED ABOUT INPUT 1
C  WOUTN2   PRINTS ADDITIONAL INFO GENERATED ABOUT INPUT 2
C  WOUTN3   PRINTS ADDITIONAL INFO GENERATED ABOUT INPUT 3
C  WOUTN4   PRINTS ADDITIONAL INFO GENERATED ABOUT INPUT 4
C  WOUTN5   PRINTS ADDITIONAL INFO GENERATED ABOUT INPUT 5
C  WOUTN6   PRINTS ADDITIONAL INFO GENERATED ABOUT INPUT 6
C  AGENO    FUNCTION RELATING AGE TO SURVIVAL
C  AGESZE   FUNCTION RELATING AGE TO SIZE
C  BLK1     BLOCK DATA FOR GENERAL PROGRAM
C  BLKO     BLOCK DATA FOR ORGANISM DEPENDENT VARIABLES
C  (NOTE: OPTIONAL SUBROUTINES LISTED UNDER APPROPRIATE SUBROUTINES)

APPENDIX B

This appendix contains the data used in the base run of the simulation model and the output for the base run. All or portions of this information is printed at the user's request. However, what appears in the following pages is an edited version of what is actually printed by the program. Data were not available to estimate all component costs of bivalve seed. Thus, to save space, only that information pertaining to algae and total feed costs is reported. In addition, the algae price computations are reported only for one month, although algae cost differences by month are reflected in the bivalve feed costs reported in subsequent sections of the output.
